The auxiliary l.t. switchgear is erected in a gallery on the turbine floor-level in the switch house, open to the main turbine room (Fig. 9) and immediately above the transformers from which it is supplied (Fig. 10). It is provided with duplicate busbars, the normal busbar being divided into four sections, one section to each transformer, whilst the transfer busbar is common to all sections. The outgoing feeders supply the various auxiliary distribution in the boiler and power plants. This switchgear is also of the metal-clad, compound-filled, horizontal draw-out type and is arranged for hand operation.

(4) *Auxiliary D.C. Supply* (460/230 *Volts*).

In order to cater for the more important auxiliary drives and particularly those requiring variable speed, e.g. the forced-draught fans, both primary and secondary, the induced-draught fans and the coal feeders, three 2 000-kW 460-volt motor-convertors are installed, space being reserved for a fourth.

These sets operate at the relatively high speed of 480 r.p.m., the current per brush arm being approximately 1 450 amperes. Normally, two convertors are running, one being fed from the auxiliary e.h.t. busbars and the other from the Newcastle Electric Supply Co.'s mains, both machines running in parallel on the d.c. side [see Section 5 (*a*)].

Protection is afforded by means of fuse time-limit overload and reverse-current trips which are so set as to ensure continuity of supply in the event of a sudden failure on either e.h.t. system. Operating experience has so far indicated that this forms a reliable and satisfactory arrangement, provided the loads on the machine are not exceptionally light, in which case variations in a.c. supply voltage are apt occasionally to cause a machine to trip out under the action of the reverse-current protection.

Control is effected from pedestals in the control room, on which are mounted a complete set of instruments and push-buttons. The closing of the main circuit-breaker causes the set to start up and synchronize, the operation being made visible in the control room by the provision of a voltmeter connected to the slip-rings, together with indicating lamps. Paralleling with the d.c. busbars is similarly effected by push-button operation, by which means the d.c. voltage is previously adjusted to the correct value.

The auxiliary d.c. switchgear is placed in line with, and in the same gallery as, the auxiliary low-tension a.c. switchgear (Fig. 9) and is situated immediately over the motor-convertors on the ground floor (Fig. 10). The positive and negative busbars are in duplicate and are mounted above and to the rear of the switchboard, with an insulated barrier between the positive and negative bars. An earthed neutral bar is also provided so that a 230-volt supply may be obtained for battery charging, switch operation, and emergency lighting.

This switchboard is of the "dead front" type with hinged sheet-metal panels and is arranged for hand operation. All circuit breakers, switches, isolating links and other live parts are mounted on a suitable structure behind the front panels, which carry the necessary instruments. A non-automatic indicating diagram is erected above the board.

(5) *Control Room.*

As may be seen from Fig. 8, the main control panels are arranged in three groups, the generator panels being distinct from the feeder panels. The three sections of the former are accommodated along the south wall of the control room, whilst the feeder panels are arranged along the east and west walls. The auxiliary e.h.t. control panels are placed along the north wall, the motor-convertor control pedestals being immediately in front of their corresponding switchgear control panels.

The generator and reducing-valve control pedestals are arranged in a semicircle in the centre of the room, around the operator's desk, and facing the generator control board. The pedestals are arranged in three groups of four each, controlling respectively a primary set, a reducing valve, a condensing set and a feed-heating set.

All control panels are of the double sheet-steel cubicle type. A gangway down the centre of the cubicles permits of easy access to all connections and is closed at each end by a sheet-steel door. This arrangement of control panels presents a very neat and simple appearance and occupies a minimum of space. On the front panel facing the operator are mounted only the indicating instruments, the red and green indicating lamps and the master control switch, all recording instruments, Merz-Price and overload relays, time-limit fuse boxes, testing terminals, integrating meters, voltage and other regulators and other such apparatus being mounted on the duplicate cubicles at the back. Thus on a feeder panel there are only an ammeter, two lamps and a switch facing the operator, with the operating diagram above, and consequently his attention is not distracted by a mass of other instruments and relays not essential for frequent reference. Along the top of the four control boards is placed a system diagram which gives the position of all isolating and selector switches and circuit breakers, these being shown by means of automatically-operated indicating discs.

In addition to the main control boards there is a further board on which are mounted various instruments for indicating and recording the pressure and flow of steam in the secondary receiver system, the water-level in the condensate tanks, etc., together with push-button control of the 48-in. main circulating-water inlet valve.

In a corner of the control room and in line with generator control panels are situated two more panels, one for the automatic frequency-control apparatus and the other for the automatic synchronizing apparatus referred to in Section 5 (*b*). The neutral-earthing switchgear control is described in Section 5 (*c*).

The alternators and transformers are equipped with current-balance Merz-Price protection, the ordinary feeders with voltage-balance Merz-Price and overload protection, the other feeders with split-conductor protection, and the motor-convertors with fuse time-limit overload and reverse-current protection. Voltage regulators are installed for each alternator. The total generated output is summated and recorded on a special recorder which also gives simultaneous records of voltage and sequence of switching operation of the individual generators. All stator temperature indicators are grouped together on the same panel as other instruments common to all machines. The telegraphs are of the electrically-operated pointer-dial type. A complete automatic telephone exchange has been installed, connecting the control room with various parts of the plant and with all substations.

The entire control room is built on the principle of a room within a room, in order to obtain quietness and cleanliness. The main entrance to it opens from the centre of a closed passage running the length of the whole of the top floor and permitting communication between the offices, model room and lavatories at one end of the bay with the offices, battery, booster and automatic telephone exchange rooms at the other end of the bay, at which end are also situated the lift and staircase. All instruments are of the flush type, finished in polished black, no nickel plating being employed anywhere. Above the control room is an internal opaque glass roof (Fig. 2) between which and the outer roof are fitted the electric lights. Any dust percolating through the outer roof settles on this internal glass roof, and gangways extending the length of the bay enable it to be easily brushed off. The steel members supporting the internal glass roof have holes in their vertical faces for exit ventilation. The outer glass roof of all bays and also the windows in the walls can be hosed by warm water supplied from a series of cocks regularly spaced along pipework forming the top handrail of gangways running around the outside of the building at window and roof levels.

Section (4). THE AUTOMATIC REGULATION OF STEAM PRESSURE AND STATION FREQUENCY.

(*a*) *Stability of Operation.*

It has already been pointed out that one of the outstanding features of the station, in fact the main outstanding feature, is the extraction from the station, for process purposes, of roughly two-thirds of the total steam passing through the primary turbines. Such an arrangement inevitably gives rise to many serious problems, not the least of which concerns the stabilizing of the process steam pressure. This problem in its original form presented itself as one of load-sharing between the primary turbines and the other turbines in the station, and it was early recognized that the maintenance of the correct steam pressure essential for process work was entirely dependent upon this factor.

Any changes in the steam load and/or the electrical load would upset conditions in the station, and it therefore became necessary to calculate the precise effects of these changes upon the process steam-supply. In doing this the relative importance of the various factors involved, such as the design of the turbine governors, the electrical frequency and the changes in the rates of steam flow through the turbines for changes in steam conditions, was revealed. It was found that the results could be expressed most conveniently in the form of partial differential equations giving the variations in frequency and process steam-pressure for given changes in steam and electrical loads. In formulating such equations, certain approximations had necessarily to be made and, as would be expected, difficulty arose in attempting to allot numerical values to certain of the partial differential coefficients from turbine-design data.

The general purpose of the analysis, however, was achieved in that it enabled the following general conclusions to be drawn:—

(1) For maximum stability the governors on the primary turbines should be coarser than those on the other turbines, to an extent proportional to the total quantities of steam passing through the two classes of turbines. Under this condition there is practically no change in steam pressure due to a change in electrical load. The same does not, of course, hold good for changes in steam demand.

(2) The greater the proportion of steam extracted from the station, the greater is the tendency towards unstable running.

(3) Instability in the mathematical sense can ensue under certain conditions of loading in combination with certain governor characteristics. These conditions were determined by equating to zero the coefficients of the differentials representing the changes either in pressure or in frequency, the coefficients being actually the same in each case.

As a result of these conclusions, the governors on the primary turbines were designed to produce a rise in speed of 9 per cent when full load is gradually thrown off, this being about 3 times the speed rise in the case of the lower-pressure turbines, the governors of which are of the usual sensitive type. This procedure in effect makes the primary turbines base-load machines and reduces to a minimum the risk of encountering a critical or unstable running condition, both steam and electrical, during the gradual growth of load on the station.

In considering the stability of turbine operation the steadying effect of the existing installation of low-pressure boilers supplying steam direct for process work was not overlooked, but it was felt desirable that the station should be as stable in itself as possible. Apart from this, the stabilizing action, which is virtually akin to a flywheel effect, can only be obtained at the expense of sudden changes in demand on this existing plant which, being of relatively small capacity, is therefore liable to priming. Mention must also be made of the stabilizing effect obtainable from the storage capacity of the large network of low-pressure steam mains supplying steam to the factory, and since the total weight of steam in these pipes amounts to about 6 tons this effect is by no means inconsiderable.

(b) *Co-ordinated Control of the Boiler Plants and Power Plant.*

Having established certain points in connection with the speed regulation of the turbines with a view to obtaining stable operation, the question arose as to which was the most suitable method of controlling the process steam-pressure, and upon this devolved the entire policy to be adopted in the method of operating not only the turbines but also the boilers.

It was finally decided that the existing low-pressure boilers should maintain a constant rate of firing, while the new high-pressure boilers should steam at a constant pressure.

There were, broadly speaking, two courses open, viz.:—

(1) The low-pressure boilers could steam at a constant pressure while the high-pressure boilers maintained a constant output.

(2) The low-pressure boilers could maintain a constant output with pressure control effected by varying the loads on the primary turbines.

The difference between these two courses is, briefly, that in the first case any fluctuations in load are taken up by the smaller boiler plant, while in the second case they are taken up by the main boiler plant which, under these conditions, must steam at a constant pressure.

The disadvantage of the first case is that any sudden large variations in load, such as are likely to occur under emergency conditions in the factory, cannot be so effectively coped with as in the second case, and for this reason, as well as for other subsidiary reasons, the second course was adjudged to be the more logical one to adopt.

It will be seen that this policy entails the control of the process steam-pressure by the power plant operatives. This can be carried out in two ways:—

(1) By altering the steam admission to the primary turbines.

(2) By altering the steam admission to the reducing valves.

The first method alters the frequency of the station as a result of the large speed regulation of the primary turbines and, further, it upsets the loads on the feed-heating turbines.

The second method is the better one as judged from these considerations alone, but on the other hand it will be appreciated that the unnecessary bypassing of steam, with the consequent loss in thermal efficiency, cannot be considered on the score of ease of control alone.

(c) *Mode of Operation of Automatic Scheme.*

In considering the question of pressure control, serious doubts arose as to whether the pressure itself would remain sufficiently stable to enable any variations to be readily followed manually by an operator or whether some form of automatic control would be necessary. It was therefore felt that a scheme which would virtually take charge of the operation of the station in a satisfactory and reliable manner under all conditions would not only ease the burden on the operating staff but would also ensure steadier conditions normally and quicker operation in an emergency.

To decide upon the type of scheme to employ which would satisfactorily meet all requirements appeared at first to be fraught with great difficulty, as at the time there was no such scheme in existence which had been designed to cope with such unusual conditions. The ordinary form of mechanical control as fitted to extraction turbines in which primary and condensing machines are combined in one unit could not be adapted to give the necessary flexibility in the case of machines forming separate units, as at Billingham, and for this reason it was decided to install a system of electrical control.

The scheme * which was finally developed and which is now installed combined a recently developed scheme † for automatic frequency control, with a means of maintaining at the same time correct pressure conditions, and is shown diagrammatically in Fig. 23.

Stated briefly, the control imparts correcting impulses to the primary turbine governor motors and reducing-valve motors in such a way as to maintain the process steam pressure at its correct value of 290 lb. per sq. in., and at the same time imparts similar impulses to the condensing machines in such a way as to maintain the station frequency at its normal value. In each case the number of impulses transmitted in unit time increases as the pressure or frequency error increases, and in this way stable control with an entire absence of any tendency towards hunting is ensured.

The operation of the control system under these conditions is therefore such that the condensing machines take up any changes in load which may be caused either by changes in electrical demand or by re-adjustments in the steam admission either to the primary or to the feed-heating turbines. It will be seen, therefore, that the output generated by these latter machines is treated purely as a by-product, their output being unaffected by any variations in the total electrical demand upon the station.

Provision is made to ensure equal sharing of load between any primary sets which may be on load, and likewise between condensing sets.

This provision is necessary because of the fact that a control impulse of given duration can hardly be expected to give, in practice, a precisely similar movement to the speeder gear of each machine when more than one machine of the same class is being operated on, in parallel. In course of time even minute differences in controlling effect might prove cumulative and be a serious source of unequal loading. To achieve equal load-sharing, each machine is provided with a relay consisting of two balanced wattmeter movements, one of which provides a torque proportional to the load of that particular generator, the other movement acting with opposing torque proportional to the average load on all generators of the same class. Contacts are provided in such a manner as to cut off "raise" impulses to any machine which may be taking more than its fair share of load, and to cut out "lower" impulses to any machine which is relatively underloaded.

---

* I.C.I.-Warren Patent No. B.P. 320038.

† Reyrolle-Warren Patent No. B.P. 303779.

During the normal running of the station it frequently happens that the primary turbines are running fully loaded with a certain quantity of steam being bypassed through a reducing valve. To cater for this condition four limit-switches are provided on the speeder-gear mechanisms of the primary turbines; these operate when these machines are fully loaded and serve to change over the pressure control from the turbines to the reducing valves. The passing-on of the control in this manner takes place entirely automatically in either direction.

Long periods frequently arise during which it is possible to generate all the load by means of the primary and feed-heating turbines alone. This possibility was not overlooked in the design of the control scheme. Under these new conditions all fluctuations in electrical load due either to changes in demand or to alterations in load on the feed-heating turbines have to be taken up by the primary turbines, and the surplus high-pressure steam, the existence of which is, of course, now a necessary condition of operation, has to be bypassed by means of the reducing valves.

To cater for this, a change-over contactor (see Fig. 23) is provided which comes into operation automatically and serves to bring into operation both the frequency control on the primary turbines and the pressure control on the reducing valves. This particular feature, which is of the greatest importance in achieving the principles of operation already laid down, is effected quite simply by the mere interchanging of certain circuits and forms an apt illustration of the essential flexibility afforded by the system of control adopted, a flexibility, moreover, which it is practically impossible to achieve in any non-electrical system.

(*d*) *Description of Automatic Scheme.*

Space does not permit a detailed description of the control apparatus itself to be given, but a general outline of the essential items will be of interest, not only because it is the first installation applied to power station control but also because of the rapid development and utilization of automatic control features in all branches of engineering which have taken place in recent years.

The pressure-control impulses are obtained by the rotation of a drum which is divided circumferentially into four segments, each of which generates impulses at a constant rate depending upon which of the four segments is in operation (see Fig. 23). The selection of drum segments is effected by means of a device responsive to steam pressure, provided with contact-making segments corresponding to those on the drum. The result of this interaction is that impulses are generated with a frequency which increases, the further the steam pressure deviates from its normal value.

FIG. 23.—Scheme for the automatic regulation of process steam pressure and station frequency.

below normal is obtained by means of a contact-making pressure-regulator of a standard type. The function of this regulator is duplicated on the pressure-responsive device operating in conjunction with the drum, so that, if either apparatus becomes faulty, control is immediately cut off before mis-operation can result.

The adjustment of the actual length of the impulses themselves is carried out by means of two time-lag relays which are so connected that the failure of one of them can at the worst only effect cessation of control and so enable the operator to put a stand-by set of apparatus into commission.

The automatic frequency-control scheme marks an important stage in the development of this type of control in this country, and the following brief description of it forms an interesting comparison with the recently evolved American schemes, some of which have now been applied to the control of power stations.[*]

In contradistinction to the prevalent American practice of generating the controlling impulse at a steady rate and graduating the control by varying the lengths of the impulse, the method employed at Billingham is to retain a fixed duration of impulse and to vary the frequency with which it occurs. Thus, if the system frequency departs from normal by 1 cycle per second, we get one impulse generated per second; in fact the actual frequency of the impulses is numerically the same as the frequency error.

In actual practice it is found that under normal conditions connection is made, broadly speaking, once every 20 seconds, though it must be remembered that this time-interval would be somewhat longer were it not for the influence of the varying loads on the primary turbines.

The standard frequency is obtained from a standard chronometer which controls the speed of a small motor-generator set by means of two movable contacts which vary the field strength of the d.c. driving motor when its speed varies slightly from the standard set by the clock. In addition, there is a quick-acting voltage-compensating device which renders the speed of the set independent of any fluctuations in the d.c. supply voltage.

The generator is wound to give a single-phase supply at 110 volts, 40 cycles, and this operates a set of relays in conjunction with a similar supply from the potential transformers connected to the running turbo-alternators. The relays act as an electrical differential device in much the same way as an ordinary synchroscope, generating the controlling impulses in the manner already described.

In common with the remainder of the automatic apparatus, the frequency-control relays and the motor-generator, together with its various controlling devices, are in duplicate, an interesting feature in this case being the provision for the automatic changing-over from one motor-generator to another in case of any trouble developing on one machine.

With a view to ensuring that the control-room attendants should have at all times a ready means of observing the behaviour of the controls, indicating lamps are provided which light up when controlling impulses are being given to the turbines or to the reducing valves. In addition, an indication of the process steam-pressure is provided on a pressure gauge mounted in a prominent position on the control pedestals, beside which is also mounted a synchroscope to indicate any deviation of the station frequency from the standard.

To convert any turbine or valve from automatic to manual operation, suitable switches are provided on each generator control panel and reducing-valve pedestal.

To cater for times when it should be necessary to operate the station entirely manually, care was taken to ensure that the task should be rendered as easy as possible for the operator. Thus the regulation of the steam admission to all turbines and reducing valves is carried out on the control pedestals, from which point the operators can observe the steam pressure, the station frequency, the generator loads and the reducing-valve openings.

In addition, indication is provided in the control room of the exhaust pressures of the feed-heating turbines, together with the levels of the water in the process condensate-tanks. These latter indications are sufficient to enable the feed-heating turbines to be regulated in accordance with the steam requirements of the evaporation plants.

The operating experience obtained during the past few months has shown that the behaviour of the plant follows very closely along the lines anticipated and it has shown, in particular, how important is the course regulation of the primary turbine governors in its effect upon the operation of the plant as a whole. The installation of the automatic control scheme, which, as already described, was rendered essential by the unusual conditions of steam and electric load requirements existing at Billingham, has been proved by experience to be fully justified, and the success which has attended its adoption may be considered to mark the beginning of a new era in power-plant control.

Section (5). OTHER SPECIAL FEATURES.

(*a*) *Alternative Auxiliary Supply System.*

The most important consideration from the point of view of continuity of supply of both steam and electricity from the power station is that of reliability of the electrical supply for driving the auxiliaries.

The normal auxiliary supply system has already been described.

Various methods of obtaining a duplicate supply were considered and it was ultimately decided to utilize the existing 11 000-volt supply from the adjacent North Tees power station. The chief difficulty arising in the utilization of this source lay in running the two supply systems in parallel, this being essential in order to avoid even a momentary interruption of supply to the auxiliaries in case of failure of the normal supply. Bearing in mind this consideration and having regard to the fact that nearly all the essential boiler-house auxiliaries require speed variation, the situation has been met by permanently connecting one 2 000-kW motor-convertor to a third or "transfer" busbar on the auxiliary e.h.t. switchgear which is supplied from a 11 000/6 600-volt transformer. The transformer is situated in one of the substations of the existing 11 000-volt network and is connected to the "transfer" busbar by a suitably protected 2 000-kVA interconnector (Fig. 22).

---

[*] R. Brandt: "Automatic Frequency Control," *Electrical World*, 23rd February, 1929; J. U. Benziger and J. T. Johnson, "Automatic Frequency Control at Mitchell Dam," *ibid.*, 29th June, 1929, and H. A. McCrea: "Automatic Control of Frequency and Load," *General Electric Review*, 1929, vol. 32, p. 309.

This motor-convertor is paralleled on the d.c. side with the remaining convertor fed from the "normal" auxiliary e.h.t. busbar and remains "floating" on the Newcastle Electric Supply Co.'s mains, i.e. its field is adjusted so that it is running light. In the event of a failure of the power station supply the normally-loaded convertor automatically shuts down and the one running from the public supply immediately takes over the load.

The total emergency load comprises the following essential auxiliaries:—

(1) Forced- and induced-draught fans (d.c.).
(2) Primary air fans, coal feeders and air preheaters (d.c.).
(3) Stand-by condenser extraction pumps (d.c.).
(4) Stand-by feed pumps (a.c.).

The motors for the first three groups are supplied from the auxiliary d.c. busbars and hence their duplicate supply is derived from the motor-convertor running on the "transfer" busbar. On the other hand, all feed pumps are driven by 6 600-volt motors supplied direct from the "normal" auxiliary e.h.t. busbars, with the exception of the two stand-by feed pumps which are supplied from the "transfer" busbar. These two pumps are able to deal with a feed-water supply sufficient to maintain three boilers on normal load, which adequately meets the factory steam demand under emergency conditions.

(b) *Automatic Synchronizing.*

Automatic frequency-control and steam-pressure regulation having been adopted as a necessity it was decided to employ a recently developed, relay-operated scheme * of automatic synchronizing of the alternators, upon the principles of which the former was based.

The method of ensuring the essential reliability of operation is unique in that it is effected by interlocking certain of the relays in such a way that the failure of any one of them renders the apparatus incapable of synchronizing the alternator. The sequence of operation is analogous to that of the combination lock on a safe, in that faulty operation at any point in the sequence prevents its completion and thus also the opening of the safe.

The speed-controlling function embodied in this apparatus is similar to the method of operation of the automatic frequency control described in Section (4), with the exception that the running machines now provide the frequency with which the speed of the incoming machine is matched. In this way quick and accurate operation, with an entire absence of any tendency towards hunting, is obtained.

To obviate any possibility of a set being "motored" when synchronized, the apparatus permits of paralleling only when the alternator is running slightly above the synchronous speed. This feature would occasionally give rise to slow operation when the alternator speed is initially below normal, as in this case exact speed-matching is obtained before synchronizing can take place. In order to prevent this the "raise speed" impulses are designed to persist for a greater length of time than the "lower speed" impulses, so that the period of exact speed-matching is materially reduced under these circumstances.

The average time taken for the apparatus to synchronize an alternator by this method, starting from the moment when the turbine is under the control of its governor, is approximately 30 seconds. This is considerably in advance of manual operation. Although both methods are available in the station, the former is looked upon by the operating staff as being a distinct asset, especially in a station of this character supplying both steam and electricity, where, in the interests of flexibility, a larger number of relatively small sets have been installed than would have been the case in a station built solely for electricity supply.

(c) *Automatic Control of Feed Pumps.*

A method * of maintaining a constant discharge pressure on the intermediate feed pumps by automatic means has been devised in the shape of a contact-making pressure regulator, the contacts of which are connected to the contactors controlling the speeds of the pumps. Direct-current control impulses are then transmitted at intervals which maintain the pump speeds at the value necessary to give the required pressure. Up to the time of writing, this feature has not been in operation, but it is expected to prove as successful as the other automatic features, of the principles of which, in fact, it is merely another application.

(d) *Battery Booster Control Scheme.*

Several of the vitally important d.c. circuits, such as those feeding the emergency lighting, the reducing-valve and governor motors and the oil-switch solenoids are fed directly from a 230-volt, 400 ampere-hour battery which is in turn coupled to the positive and neutral wires of the main d.c. supply through a contactor fitted with reverse-current protection (Fig. 24).

The battery is charged by means of a reversible booster which is also used to maintain the voltage of the battery busbars at the normal value during such times as the battery is disconnected from the main supply, this being done by means of a voltage regulator operating on a separate exciter coupled to the main shaft. Under normal working conditions the battery is left floating, the number of cells being so chosen that when fully charged they take a small "trickle" charge which is just sufficient to maintain the plates in a healthy condition.

The control of the battery and booster represents a divergence from normal practice in certain respects. In the first place it was found to be possible to dispense altogether with the usual buffer resistance by suitably designing the various control circuits. In order to appreciate how this could be done it is sufficient to remember that no danger exists in momentarily short-circuiting the booster during the running-up period before the field circuit is energized. On the other hand, there is no disadvantage in open-circuiting the battery circuit altogether while the booster bars are in parallel with the main d.c. supply or, in other words, when the line contactor is closed. By adopting such a procedure the heavy current which would otherwise circulate through the booster armature when short-circuited, with a residual field current still flowing, would cause damage and necessitate the provision of the buffer resistance, the use of which this scheme avoids.

---

* Reyrolle-Warren Patent Nos. B.P. 294970 and 294971.

* I.C.I.-Warren Patent No. B.P. 324156.

A further interesting feature relates to the automatic change-over from the hand control of the booster excitation to the automatic control if trouble develops on the main d.c. system while the battery is being charged. In the ordinary way it is necessary for the attendant to stand by during charging periods ready to change the action of the booster from negative to positive in case the services of the battery are suddenly required. Complete automatic operation, however, in conjunction with an alarm device is certainly preferable and in this case has never failed to give every satisfaction since it was installed.

A = reverse-current circuit-breaker.
B = booster motor contactor.
C = booster contactor.
D = booster short-circuiting contactor.
E = first motor-starting contactor.
F = second motor-starting contactor.

(e) *Neutral Earthing Scheme.*

The neutral points of the 8 alternators are connected to a common earth-bar via single-pole, oil-immersed, compound-filled, metal-clad switches incorporating the neutral bar. The latter is connected to the earth plates through a grid resistance of 2·78 ohms. In the event of a fault in the resistance it can be short-circuited, thus connecting the system directly to earth.

The "neutral earth" comprises two banks of earth tubes, each consisting of six 2-in. bore cast-iron pipes, 6 ft. long, buried in the ground on the south side of the station. An instrument panel is provided for periodical measurement of the resistance between the two banks. In addition, all electrical apparatus in the station itself is connected to copper earth-bars running systematically around the station on lightly insulated supports, these bars being connected direct to two further "station earth" banks which are separate from the "neutral earth" banks.

The oil switches and the resistance are situated on the ground floor of the switch house, adjacent to the station reactors, and are remote-controlled from their respective generator panels in the control room on the top floor. Hand operation of any generator control switch trips the main oil switch and the neutral switch, whilst operation of the Merz-Price relay on the occurrence of a fault trips the main oil switch, the main field circuit-breaker and the neutral switch.

The neutral earthing scheme is automatic in operation and provides the following features:—

(1) One only of the five 12 500-kW alternators can be earthed at a time.

(2) Selection of the machine to be earthed follows a definite order, depending upon the number and type of machines on load, the arrangement ensuring that a condensing set will always be earthed in preference to a primary set, and also that a primary set will only be earthed when no condensing set is running.

(3) When the main switch and consequently also the neutral switch of the earthed machine trips, the neutral switch of another running machine is automatically closed.

(4) If for any reason the system is left unearthed, a combined audible and visual alarm is operated.

The second feature was specially devised because of the different characteristics of the various generating sets.

(f) *Special Instruments.*

Wherever possible, special instruments developed by Synthetic Ammonia and Nitrates, Ltd., for use in factory processes, have also been adopted in the boiler and power plants, especially steam and water flowmeters. Standard practice throughout the factory with regard to temperature measurements has also been followed, viz. resistance thermometers up to 600° F., iron-constantan thermo-couples up to 1 500° F., and chromel-alumel thermo-couples above 1 500° F.

The following cases, however, were outside the scope of the company's standard apparatus and practice:—

Boiler Plant.—The boiler control panels are equipped with well-known combined steam-flow, air-flow recorders, 9-point draught gauges, and motor-driven electrical CO_2 recorders.

Power Plant.—Electrically-operated process steam-flow recorders are installed in the control room, together with pressure gauges actuated on the repeater system and also feed-tank level gauges.

CONCLUSION.

It is impossible to describe in detail every feature of the Billingham plant, and consequently in the preceding pages the authors have in a general manner dealt only with the most outstanding features. The information given, however, will reveal that the Billingham steam and electric power plant constitutes an important advance in the design of high-pressure, high-temperature power plants. Credit is due to the various contractors for the readiness and courage with which they met the multitude of new problems involved, especially in view of the short time available, and also to the research department of Synthetic Ammonia and Nitrates, Ltd., for the work carried out there, especially that in connection with pipework.

The authors desire to record their appreciation of the assistance rendered in the compilation of this paper by the following members of the staff of Synthetic Ammonia and Nitrates, Ltd.: Messrs. S. Boyle (photographs, etc.), G. H. Corner, H. J. Churchman, B.Sc., D.I.C., J. Johnston, H. Rissik, B.Sc., and T. R. Warren, B.A., B.Sc. (automatic control features).

APPENDIX 1.

Efficiency Calculations.

(1) *Boiler Efficiency.*

Heat power supplied by the combustion of 1 280 tons per day of coal having a calorific value of 11 700 B.Th.U. per lb.

$$= \frac{1\,280 \times 2\,240 \times 11\,700}{24}$$

= 1 396 000 000 B.Th.U. per hour

= 409 500 kW

Total heat of steam at 645 lb. per sq. in. abs. and 833° F. = 1 425 B.Th.U. per lb.

Total heat of feed water at 401° F. = 375 B.Th.U. per lb.

Therefore heat power supplied to 1 075 000 lb. per hour of steam

= 1 075 000 × (1 425 − 375) B.Th.U. per hour

= 1 128 000 000 B.Th.U. per hour

= 331 000 kW

$$\text{Boiler efficiency} = \frac{\text{Heat power supplied to steam}}{\text{Heat power supplied by coal}}$$

$$= \frac{331\,000}{409\,500} = \underline{81 \text{ per cent}}$$

(2) *Overall Thermal Efficiency.*

Power in steam to turbo-alternators (Appendix 3) = 59 150 kW

Power in steam to process plants = 82 550 kW

Total available steam power, less power to feed heaters and pumps (Appendix 2) = 141 700 kW

Therefore proportion of total steam power

$$\text{taken by turbo-alternators} = \frac{59\,150}{141\,700} = 0{\cdot}4175$$

Proportion of heat power in coal converted to electrical power = 409 500 × 0·4175 = 170 900 kW

Electrical power generated (Appendix 3) = 43 500 kW

Proportion of electrical power taken by auxiliaries = 2 200 kW

Therefore electrical power available at busbars = 41 300 kW

$$\textit{Overall Thermal Efficiency} = \frac{\text{Electrical power available}}{\text{Heat power required}}$$

$$= \frac{41\,300}{170\,900} = \underline{24{\cdot}22 \text{ per cent}}$$

$$\text{Alternatively, efficiency} = \frac{\text{Electrical power generated}}{\text{Heat power required}}$$

$$= \frac{43\,500}{170\,900} = 25{\cdot}45 \text{ per cent}$$

APPENDIX 2.

Increase in Thermal Efficiency due to Feed-Heating and to Increased Temperature and Pressure.

If it is assumed that to generate steam under different conditions of temperature and pressure, and from different feed temperatures, 1 280 tons per day of coal having a calorific value of 11 700 B.Th.U. per lb. are burned when the boiler efficiency is 81 per cent, then the following comparison of thermal efficiencies can be made:—

Case (1). *Steam Generated at* 290 *lb. per sq. in. abs. and* 653° *F. without Feed-heating.*

Heat supplied to steam .. .. = (Total heat − Heat in feed water at 84° F.)
= (1 340 − 52) = 1 288 B.Th.U. per lb.

Heat power given to steam (see Appendix 1) = 1 128 000 000 B.Th.U. per hour

$$\therefore \text{ Steam generated} \quad = \frac{1\,128\,000\,000}{1\,288} = 874\,000 \text{ lb. per hour}$$

Energy in the steam * .. .. = 448 B.Th.U. per lb.

∴ Theoretical power available .. .. .. = 874 000 × 448
= 391 000 000 B.Th.U. per hour
= 114 500 kW

Allowing for the power taken by the feed pumps, the total steam power available .. .. = 113 600 kW

---

* The energy in the steam is here defined as the energy which is theoretically available from it when it expands adiabatically from its initial temperature and pressure to the final condensation temperature of 84° F.

Case (2). *Steam Generated at* 290 *lb. per sq. in. abs. and* 653° *F. with Single-stage Feed-heating to* 176° *F.*

Heat supplied to steam .. .. = (1 340 − 144) = 1 196 B.Th.U. per lb.

Steam generated .. .. = $\frac{1\,128\,000\,000}{1\,196}$ = 942 000 lb. per hour

The energy in the steam is 448 B.Th.U. per lb. as in Case (1); if we assume that 10 per cent of the total steam is withdrawn from the turbine at 185° F. for feed-heating purposes, then

Theoretical power available .. .. .. = (942 000 × 448) − (94 200 × 157)
= 407 000 000 B.Th.U. per hour
= 119 400 kW

Allowing for the power taken by the feed pumps,
the total steam power available .. .. = 118 400 kW

Case (3). *Steam Generated at* 645 *lb. per sq. in. abs. and* 833° *F. without Feed-heating.*

Heat supplied to steam .. .. = (1 432 − 52) = 1 380 B.Th.U. per lb.

Steam generated .. .. = $\frac{1\,128\,000\,000}{1\,380}$ = 822 000 lb. per hour

Energy in the steam .. .. = 538 B.Th.U. per lb.
Therefore theoretical power available .. .. = 822 000 × 538
= 444 000 000 B.Th.U. per hour
= 130 000 kW

Allowing for the power taken by the feed pumps,
the total steam power available .. .. = 128 100 kW

Case (4). *Steam Generated at* 645 *lb. per sq. in. abs. and* 833° *F., with* 7-*Stage Feed-heating to* 401° *F., i.e. Power-Plant Conditions.*

Heat supplied to steam .. .. = (1 432 − 409) = 1 023 B.Th.U. per lb.

Steam generated .. .. = $\frac{1\,128\,000\,000}{1\,023}$ = 1 075 000 lb. per hour

The energy in the steam is 538 B.Th.U. per lb. as in Case (3); here, again, allowance must be made for the steam supplied to the feed-heaters before the theoretical power available can be arrived at. The steam power taken by the various stages of the feed-heating system is detailed in Table 10, from which it is seen that the total steam power supplied for regenerative feed-heating purposes is 86 500 000 B.Th.U. per hour, or 25 350 kW.

Therefore theoretical power available .. .. = (1 075 000 × 538) − 86 500 000 B.Th.U. per hour
= 169 250 − 25 350 kW
= 143 900 kW

Allowing for the power taken by the feed and extraction pumps, the total steam power available .. .. = 141 700 kW

TABLE 10.

Stage	Steam supplied to	Steam conditions		Energy in steam	Steam quantity	Theoretical steam power

APPENDIX 3.

TECHNICAL DATA.[*]

(*a*) COAL PREPARATION PLANT.

Coal-conveying capacity	4 800 tons/day (4 880 tonnes[†]/day)
Coal-pulverizing capacity	3 240 tons/day (3 290 tonnes/day)
Pulverized-coal consumption (normal)	1 280 tons/day (1 300 tonnes/day)

Raw-coal feed hopper.

The hopper accommodates three 100-tons/hour skip hoists and has a 1¼-in. gap between screening bars.

Skip hoists.

Number installed	3
Number working	2
Capacity	100 tons/hour (101·6 tonnes/hour)

Belt conveyors.

Number installed	2
Number working	2
Capacity	160 tons/hour (163 tonnes/hour)
Belt speed	300 ft./min. (1·52 m/sec.)
Belt width	30 in. (71 cm)

Raw-coal bunker.

Total capacity	1 068 tons (1 084 tonnes)
Number of discharge openings	12

Pulverizers.

6 roller mills installed; capacity	13½[‡] tons/hour (13·7 tonnes/hour)
3 roller mills working; normal output	10·8 tons/hour (11·0 tonnes/hour)
4 ball mills installed; capacity	13½[‡] tons/hour (13·7 tonnes/hour)
2 ball mills working; normal output	10·5 tons/hour (10·7 tonnes/hour)
10 mills installed; total capacity	3 240 tons/day (3 290 tonnes/day)
5 mills working; total normal output	1 280 tons/day (1 300 tonnes/day)

Pulverized-coal bunkers.

Number installed	8
Capacity	60 tons (61 tonnes)

(*b*) BOILER PLANT.

Coal burned	1 280 tons/day (1 300 tonnes/day)
Calorific value of coal	11 700 B.Th.U./lb. (6 500 tonne-cals./tonne)
Feed-water supplied	1 093 400 lb./hour (11 900 tonnes/day)
Steam generated	1 075 000 lb./hour (11 700 tonnes/day)
Blow-down loss	18 400 lb./hour (200 tonnes/day)

Boilers.

Number of boilers installed	8
Number of boilers working	5 (1 standing by; 1 cleaning; 1 spare)
Type	4-drum, with water screens and Murray water-cooled walls
Water capacity	98 000 lb. (44·5 tonnes)
Normal working pressure	715 lb./sq. in. abs. (50·3 kg/cm^2)
Maximum working pressure	815 lb./sq. in abs. (57·3 kg/cm^2)
Boiler heating surface	7 640 sq. ft. (710 m^2)
Heating surface of screens and walls	2 380 sq. ft. (221 m^2)
Total heating surface	10 020 sq. ft. (950 m^2)
Actual evaporation	215 000 lb./hour (normal) to 270 000 lb./hour (max.) (97·5 tonnes/hour to 122 tonnes/hour)
Actual evaporation, in lb./sq. ft. per hour	21·2 (normal) to 26·8 (max.)
(Actual evaporation, in kg/m^2 per hour)	(503 to 621)
Factor of evaporation	1·1

---

[*] British Standard Units are employed throughout. The corresponding metric units are given in brackets.

[†] One tonne = 2 204 lb.

[‡] 15 American tons = 13½ English tons.

Combustion chambers (arch-less type).

Volume above water screen	12 800 cub. ft. (362 m^3)

	Normal load	Maximum load
Dry coal fired	119 500 lb./hour (54·3 tonnes/hour)	150 000 lb./hour (68 tonnes/hour)
Dry coal fired per cub. ft. of combustion chamber	9·35 lb./hour	11·7 lb./hour
(Dry coal fired per m^3 of combustion chamber)	(150 kg/hour)	(188 kg/hour)

Economizers (steaming type).

Heating surface	23 030 sq. ft. (2 140 m^2)

	Normal load	Maximum load
Water inlet temperature	401° F. (205° C.)	401° F. (205° C.)
Water outlet temperature	523·4° F. (273° C.)	523·4° F. (273° C.)
Gas inlet temperature	1 150° F. (621° C.)	1 150° F. (621° C.)
Gas outlet temperature	600° F. (315·5° C.)	640° F. (338° C.)
Draught loss	0·885 in. H_2O (0·00225 atmo.)	1·375 in. H_2O (0·0035 atmo.)
Coefficient of heat transfer	1 250 B.Th.U./sq. ft./hour (3 380 kg-cals/m^2/hour)	1 550 B.Th.U./sq. ft./hour (4 210 kg-cals/m^2/hour)

Superheaters (combined radiant-heat and convection type).

Heating surface	5 000 sq. ft. (465 m^2)

	Normal load	Maximum load
Initial steam temperature	523·4° F. (273° C.)	523·4° F. (273° C.)
Final steam temperature	850° F. (455° C.)	856° F. (458° C.)
Coefficient of heat transfer	893 B.Th.U./sq. ft./hour (2 420 kg-cals/m^2/hour)	1 110 B.Th.U./sq. ft./hour (3 010 kg-cals/m^2/hour)

Air preheaters (rotary type).

Heating surface	37 000 sq. ft. (3 440 m^2)

	Normal load	Maximum load
Gas quantity at inlet	7 300 000 cub. ft./hour (206 600 m^3/hour)	9 700 000 cub. ft./hour (276 000 m^3/hour)
Gas quantity at outlet	5 130 000 cub. ft./hour (145 300 m^3/hour)	6 850 000 cub. ft./hour (194 000 m^3/hour)
Gas temperature at inlet	600° F. (315·5° C.)	640° F. (338° C.)
Gas temperature at outlet	230° F. (110° C.)	255° F. (124° C.)
Air quantity at inlet	3 650 000 cub. ft./hour (103 400 m^3/hour)	4 680 000 cub. ft./hour (132 800 m^3/hour)
Air quantity at outlet	5 820 000 cub. ft./hour (165 000 m^3/hour)	7 650 000 cub. ft./hour (216 900 m^3/hour)
Air temperature at inlet	60° F. (15·5° C.)	60° F. (15·5° C.)
Air temperature at outlet	500° F. (260° C.)	520° F. (271° C.)
Coefficient of heat transfer	715 B.Th.U./sq. ft./hour (1 935 kg-cals/m^2/hour)	922 B.Th.U./sq. ft./hour (2 635 kg-cals/m^2/hour)

De-dusters.

	Normal load	Maximum load
Gas quantity	5 130 000 cub. ft./hour (145 300 m^3/hour)	6 850 000 cub. ft./hour (194 000 m^3/hour)
Gas velocity	10 ft./sec. (3·05 m/sec.)	13·5 ft./sec. (4·12 m/sec.)

Stacks.

Effective diameter	8 ft. (2·44 m)
Effective area	50 sq. ft. (4·65 m^2)
Stack height	132 ft. (40·3 m)
Gas velocity (normal load)	28 ft./sec. (8·5 m/sec.)

(c) ASH REMOVAL PLANT.

Main ash sluice.

Ash quantity (dry)	160 tons/day (162·5 tonnes/day)
Water quantity	161 500 galls./hour (734 m^3/hour)

Slurry whirl pit.

Pump capacity (normal)	220 500 galls./hour (1 000 m^3/hour)
Head (normal)	32·5 ft. (10 m)

Ash settling pit.

Capacity	12 500 cub. ft. (345 m^3)
Water velocity	3·28 ft./min. (1 m/min.)
Overhead grab crane capacity	45 tons/hour (45·7 tonnes/hour)

Ash ropeway system.

Ropeway capacity	45 tons/hour (45·7 tonnes/hour)

(*d*) HIGH-PRESSURE (PRIMARY) TURBO-ALTERNATORS.

Number installed	3
Number working	2
Maximum continuous rating	12 500 kW
Steam conditions at inlet	645 lb./sq. in. abs. and 833° F. (45·3 kg/cm^2 and 446° C.)
Steam conditions at exhaust	290 lb./sq. in. abs. and 653° F. (20·4 kg/cm^2 and 345° C.)
Total steam flow	1 075 000 lb./hour (11 700 tonnes/day)
Total theoretical steam power available	32 100 kW
Total electrical output	23 800 kW
Percentage of maximum continuous rating	95·2
Turbine efficiency	76·5 per cent
Alternator efficiency	96·9 per cent
Overall efficiency	74·2 per cent

(*e*) CONDENSING TURBO-ALTERNATORS.

Number installed	2
Number working	1
Maximum continuous rating	12 500 kW
Inlet steam conditions	290 lb./sq. in. abs. and 653° F. (20·4 kg/cm^2 and 345° C.)
Exhaust steam conditions	0·58 lb./sq. in. abs. and 84° F. (0·04 kg/cm^2 and 29° C.)
Condenser vacuum	28·82 in. Hg (730 mm Hg)
Dryness fraction at exhaust	0·89
Total steam flow	104 000 lb./hour (1 130 tonnes/day)
Total theoretical steam power available	13 450 kW
Total electrical output	10 200 kW
Percentage of maximum continuous rating	81·6
Turbine efficiency	78·5 per cent
Alternator efficiency	96·7 per cent
Overall efficiency	75·9 per cent
Cooling water temperature (inlet)	59° F. (15° C.)
Cooling water temperature (outlet)	79° F. (26° C.)
Cooling water, quantity	75 750 cub. ft./hour at 59° F. (2 115 m^3/hour at 15° C.)

(*f*) FEED-HEATING TURBO-ALTERNATORS.

Number installed	3
Number working	2
Maximum continuous rating	6 000 kW
Inlet steam conditions	290 lb./sq. in. abs. and 653° F. (20·4 kg/cm^2 and 345° C.)
Exhaust steam conditions	12·73 lb./sq. in. abs. and 205° F. (0·9 kg/cm^2 and 96° C.)
Dryness fraction at exhaust	0·992
Total steam flow (inlet)	241 000 lb./hour (2 620 tonnes/day)
Total steam flow (exhaust)	107 000 lb./hour (1 166 tonnes/day)
Total theoretical steam power available	13 600 kW
Total electrical output	9 500 kW
Percentage of maximum continuous rating	79·2
Turbine efficiency	73·5 per cent
Alternator efficiency	95·5 per cent
Overall efficiency	70·2 per cent

(*g*) FEED-HEATING SYSTEM AND DISTILLATION PLANT.

Number of sets installed	3
Number of sets working	2
Total feed water output	1 093 000 lb./hour (11 900 tonnes/day)
Feed water conditions (normal)	820 lb./sq. in. abs. and 401° F. (57·7 kg/cm^2 and 205° C.)
Total raw water supplied	230 000 lb./hour (2 512 tonnes/day)
Total distillate gained	209 000 lb./hour (2 276 tonnes/day)

* Steam leaves heaters as condensate.

Discussion before The Institution, 13th March, 1930.

Mr. C. H. Merz: The designers of this plant have had a great deal of experience beyond that involved in the lay-out of power stations, as is shown by the varied and original way in which they have approached the problems before them. Some of the points specially referred to as novel are, perhaps, not quite so novel as would appear. For instance, the cable tunnels are in accord with recent practice in power stations in various parts of the world. The designers of plant of this kind have first to decide whether they are going to plan it as a self-contained plant, relying on its own resources for almost all purposes, or whether they propose to adapt it for work in conjunction with any outside system. In this particular case, due, I believe, largely to the fact that the question of periodicity was uncertain in the locality concerned, the designers decided to lay out the whole plant as a separate entity—a fact which must be borne in mind when it is subjected to technical criticism. They have adopted what may be described, in comparison with ordinary power-station practice, as a horizontal lay-out. An unusual feature of the plant is that it is spread over a large area; it is open to question as to whether this is good practice, and whether, if there were room, the average power station would be improved by the adoption of this kind of design. There are obvious reasons, in addition perhaps to those of finance, why the designers adopted it in this case. The plant had to be constructed in the minimum of time, and the adoption of this lay-out, of standard buildings, etc., clearly facilitated rapid erection. When time, however, is not of such importance, or when the designer has a free hand, the questions of cost and of the operating results of the plant must be considered. It is clear to me that the capital cost involved by this method of lay-out of power plant is considerably higher than that of established practice, and a greater weight of steel is involved. What is equally important, from actual experience of plant in which the component parts of the equipment are spread about, I can say that the operating costs will be materially higher, so that I do not feel inclined to support this departure from a conventional lay-out. Regarding the general question of the steam cycle, the steam pressure is greater than that hitherto employed in this country for plant at all approaching this size. The first high-pressure plant using feed heating and the other general characteristics of the steam cycle now adopted as standard in power stations, was installed some 10 years ago at the North Tees station, adjacent to this plant. It was based upon suggestions of the late Dr. Ferranti, who had thought out the matter in considerable detail many years previously. I do not think that this side of his work has been recognized as freely as some of the others, although it had its recognition in the United States, I am glad to say, in a very substantial way. The steam pressure adopted in this plant is 30 per cent higher than that of the original North Tees plant, and is an advance upon other designs. Why has there not been a greater advance in this country in the direction of higher pressures? So far as my own experience over several years is concerned, it cannot be in any way due to troubles with the high pressure, nor with any of what were in the past the unusual elements of the steam cycle, including reheating. As is pointed out in the paper, if a higher pressure had been attempted it would have involved reheating, and I think that if I were associated with the work of designing a plant of this description, which is required to run independently, I should probably agree with the authors in avoiding reheating. Whilst at first sight it would seem that the complication and the capital cost of the turbines adopted are greater than for high-pressure turbines bled in the usual way, it must be recognized that in this case the average efficiency of the plant under somewhat changing conditions had to be considered. Doubtless, the adoption of the separate feed-heating turbines has simplified the matter from that point of view: over the average life of the plant, which is of primary importance, it will probably prove to be an economical arrangement. The authors claim that this plant is estimated to produce electricity at lower cost than any other coal-fired station in the world. That claim cannot be substantiated, as there are several coal-fired stations in different parts of the world which are to-day producing energy far more cheaply than this plant ever can produce it, as the cost is largely settled by the price of fuel. The plant is several times described in various parts of the paper as unusual. It has been designed, as I have said, to meet unusual conditions, but I suggest that the design itself will also prove to be unusual. I do not think that, as a general rule, such a plant would again be designed to run almost entirely as a separate entity. It is clear that much of the complication and consequent large capital cost of the plant arises from the fact that the designers have had two conditions continually before them: the first is the correct regulation of the supply of process steam so as to provide for the right quantity of this, and the second is the necessity of maintaining a proper supply of electrical energy. I suggest that if the designers had not been limited or controlled by the conditions to which I have referred, and if the grid had been in existence, a far more efficient method of dealing with the problem could have been adopted. This method would, I feel sure, be applied in the future, if such a case should ever again arise. In the proposed method the process steam is considered as the main and only problem of the special plant, and its amount is regulated to suit the needs of the process without regard to the quantity, large or small, of the electricity generated. The process steam which is not required by the process itself is used to generate electricity for the grid, and any deficiency in the electricity generated by the process steam at any time is taken from the grid. This, I feel sure, is the correct general solution and it is unfortunate that such an important plant as that described in the paper had to be built at a time when these principles could not even be considered. This general principle has governed the design of the waste-heat plants which have been running for many years on the North-East Coast, where in essence the problem is the same as that at Billingham. It was adopted for the Mersey Power Company's plant some 18 years ago; this installation supplies process steam in a very similar way to that adopted in the Billingham plant and is to-day producing energy at a cost which is one of the lowest in the country.

Mr. W. M. Selvey : I agree with Mr. Merz that the idea of cable tunnels and tunnel floors is not new. I am pleased to see that absolute pressures are used in the paper, but I am relieved to find that absolute temperatures are not employed. With regard to the provocative statement that this station can produce current more cheaply than one of standard design, I think the authors have not made their meaning clear. Apparently, the idea which is intended is that by the combination of process steam and electricity a better overall figure is obtained than would have been the case if the grid had been available and the balance of the current had been purchased from the grid supply. On the question of the design, I agree with Mr. Merz in the opinion that the horizontal lay-out will not necessarily be the standard practice of the future. I appreciate the fact, however, that the Billingham plant is endowed with two very marked features. The first is the enormous array of change-over pipes on the steam side—a feature which was necessary because the designers were not only committed to this kind of steam plant, but they had also to make full use of the boiler equipment already in existence. Secondly, there is the fact that the high-pressure boilers have to be supplied with a large amount of "make-up" distilled feed-water. It would appear, from the fact that the ideas of the authors have actually come into effect, that pulverized fuel is now firmly established, despite the critical attitude of the public. From what the authors have said, it seems that when striking advances were made in other directions the pulverized-fuel scheme was almost automatically adopted as part of the equipment. It is disappointing to find that interesting details as to pulverization are dismissed in so few words at the beginning of Section (3); information, particularly as to the heating mills and the type of mills used in the pulverization system, has been omitted. Any further facts that the authors could supply in this connection, would be welcome. The design of the superheaters is interesting, and in this connection it is well known that an experimental superheater which is running at a pressure of about 1 000° F. has been made at Detroit. All kinds of special devices are being tested in order to find out whether the advantages of economy can be obtained by higher superheating temperatures without increase of pressure. The authors have decided to go half-way, and great ingenuity has been shown in the construction of the type of superheater in use at Billingham. There is another advance in the simplicity shown by the apparatus; by means of the steaming economizer it has been possible to eliminate the baffles in the pulverized-fuel boiler. The authors have referred to the design of the turbine shown in Fig. 20 to the effect that it had great merits, but that it was not the object of the paper to enter into the question of turbine design. I am interested in that turbine—a machine which, I think, should provide some unusual results. On page 1264 the great advance which has been made in turbine governors is mentioned. It is well known that in cases where the power passing through the turbine is large compared with the inertia of the rotor, the question of governors has given rise to considerable apprehension among turbine designers. The system of governors in use at Billingham represents an important advance in this direction. It is a big achievement that a plant of this kind should have been erected in Great Britain, where we have the habit of depreciating ourselves. The success is a result, I suppose, of the rationalization which Lord Melchett has been so successful in bringing about; and it shows what can be done when adequate resources are available. Even although its output capacity of 37 500 kW or 50 000 kW is not that of a super-station, the Billingham installation is very impressive as a private plant.

Mr. T. R. Warren : I think that a limit will eventually be reached beyond which it will not be possible further to improve thermal efficiency, at least while steam is used as the working fluid. A great deal still remains to be done, however, to reduce working costs, and I can foresee further developments in the design and utilization of automatic features to this end. Many other considerations render it essential to develop improved methods of operation, if we are to keep pace with the rapid advances now being made in all fields of power generation and transmission. The paper shows the important part played by governing characteristics in the operation of a compounded station, and throws new light on many problems concerning the stability and operation not only of power stations but also of power systems. With regard to Mr. Merz's observations in connection with the grid, if the Billingham station had been linked with an outside supply the steam pressure would have been affected by changes in the system frequency and this would have led to difficulties. Automatic frequency control, as described in the paper, offers decided advantages in the control of power systems. The number of stations capable of being conveniently interconnected is at present limited owing to serious difficulties in regard to control. I think, however, that as improved methods become available this number will be increased without the formation of systems too unwieldy to be handled. Only in this way, in my opinion, can the full benefits resulting from interconnection be realized.

Mr. H. W. Clothier : I suggest that the authors show on Fig. 15 how any turbine can be supplied from any boiler by the addition of the boiler connections to the diagram. The paper describes a station designed with a typically British regard for safety. The use of secondary steam for process work introduces new features, but, apart from these, there are other noticeable items associated with the special precautions, attributable to the designers' purpose in providing a system in which the provision of an unfailing supply was to be of supreme importance. Having regard to the three main requirements, safety, reliability and extra service in providing process steam, it is significant that the designers have employed complete automatic control. The form of control adopted has been built up round two fundamental devices in the development of which Mr. Warren has taken a prominent part. The first is the sequential automatic synchronizer; unlike the Continental synchroscope, it operates by means of definite relays, as illustrated in Fig. 23, and it has been explained that the rate of control is proportional to the frequency error. The use of sequential relays is an advance, I think, upon the method of permissive control; here the contact works between the two fingers and there may be a lag in the movement which establishes hunting—an effect which is absent from the sequential relay mode of synchronizing. The second is the master frequency control incorporating a separate motor-generator, which is kept in step by means of a master clock and also functions through sequentially operated relays of an identical pattern to those used for the automatic synchronizer. The essential feature of these automatic systems is the use of simple reliable relays with unfailing contacts for making connections and correctly reproducing the corresponding manual operations. At every stage it should be possible to convert the automatic action to manual operation by a switch. The paper and the slides suggest the possibilities of applying these developments to ordinary power-station circuits. I should like to ask the authors whether their experience in the operation of this apparatus is sufficient to warrant their recommending its application to ordinary power-station service. Frequency control would appear to have a particular field of service in the interconnection of large generating stations, and more so in dealing with the difficult problem of load-sharing, and control by frequency regulation of generating stations in parallel. It seems to me that the present hand control must involve a great amount of human responsibility and worry, particularly at times of emergency, whereas when responsibility is taken by automatic means the burden on many men's minds is at once relieved. The automatic work is performed in a predetermined way and in a fraction of the time taken by manual operation. The predetermined way arising out of such pioneer work as described by the authors is, as it were, a storage of brain capacity in mechanical equipment, the store being made available for constant and instant emergency service. Whether the emergency takes the form of sudden changes in load location, results of abnormal condition, or faults on the steam and electrical side, the automatic control should be equally effective. The schemes tried by the authors, with the addition of the necessary pilot wires, contain all the elements for "Centrovisory," load-sharing and automatic frequency control, for example, in a distribution system such as the British grid where all the generating plant would be kept in step within narrow limits. This condition would be particularly helpful in synchronizing any two sections of the network; even automatic synchronizing of sections would be possible, and, incidentally, when delays due to faults can be reduced to a negligible amount an efficient public time service may be provided as well.

Mr. H. Rissik: With regard to the removal of the ash dust from the boiler flue gases, of the three methods available for dealing with this problem that of dry separation by centrifugal means is the most common in this country. It has the disadvantage that it deals effectively with only the larger particles of grit and requires a relatively large consumption of power, i.e. about 25 to 30 kW per ton of coal burnt per hour. In view of present high boiler ratings this fact must not be lost sight of, especially as a de-dusting efficiency greater than 90 per cent is seldom obtained. By far the simplest and most satisfactory method is that of electrostatic precipitation of the ash particles. Chiefly on account of its higher initial cost this method has as yet found little favour in this country, although it is used extensively abroad and particularly in Germany, where the cost of an installation having a guaranteed efficiency of 90 per cent varies from 15 to 20 shillings per sq. ft. of boiler heating surface. In contradistinction to centrifugal systems, the de-dusting efficiency decreases with rising boiler load. At Trenton Channel, for example, an efficiency of 90 per cent is readily obtained at normal load, but this falls to 75 per cent at 30 per cent overload. The latest installation at Klingenberg has a de-dusting efficiency of 96 per cent and deals with more than 12½ million cubic feet of flue gas per hour. The two foregoing methods have the common disadvantage that they do not in any way alleviate the damage to vegetable life from sulphurous fumes emanating from boiler stacks. The method of dust removal by contact with either a spray or a falling film of water undoubtedly gets rid of sulphur dioxide from the flue gases at the same time. Wet de-dusters of the water-spray type are the more common, the water quantity required being about 10 per cent of the boiler load. The system employing a falling water-film, of which that at Billingham is the first to be installed in this country, is certainly the most promising, as a de-dusting efficiency of 90 per cent is obtained together with a sulphur dioxide removal of 30 per cent. On the other hand, the quantity of water required (25 lb. per 1 000 cub. ft. of flue gas) to give satisfactory results is in most cases prohibitive, being comparable in amount to the boiler feed-water supply. To power station engineers the most interesting features of the Billingham plant are, I think, the simultaneous automatic control of station frequency and process steam pressure, and the unorthodox arrangement of the high-pressure and intermediate-pressure pipework systems. With regard to the former, the method adopted is novel and, being inherently more flexible, is undoubtedly of wider application than the system of automatic control recently developed in the U.S.A., for the distribution of steam from industrial power plants which are tied into an electrical network. The American system is, nevertheless, ingenious in that it maintains constant the pressure at the exhaust and extraction outlets of turbo-generator sets in which the output depends entirely upon the demand for extracted or exhaust steam. At the same time, it allows of instantaneous transfer from steam-pressure control to speed control independent of steam pressure, without causing a rise in speed of the turbines. In connection with the authors' remarks on pipework lay-out, it should be noted that the Detroit Edison Company have also had recourse to building a scale model of their new 100 000-kW plant, and with precisely the same object in view, namely, to facilitate the design of the pipework system. It would be interesting to know how far this procedure has become common practice in the design of modern power plant in this country.

Mr. T. S. Blenkinsop (*communicated*): The results achieved by the Billingham plant are well in advance of any others obtained in this country. A great amount of skill was involved in the design and lay-out of the pipework, not only in the power station itself but also in the works, although the latter, which is of more conventional construction as regards pressure and temperature, did not involve factors so unknown as entered into the design of the power station. I should be glad to know why the high-pressure steam ranges were pulled up on erection to an amount equal to the full expansion of the pipe between anchors, whereas the high-pressure feed and intermediate-pressure steam ranges were only pulled up to half this amount. I should also like to know why, in the case of the flanges, a 10-in. steam flange was made 6 in. thick, whereas a 10-in. feed flange for the same pressure was only made 3 in. thick. The type of high-pressure joint adopted is of special interest, and the results confirm my own experience of the efficiency of a similar construction when other more elaborate and costly types of joints have failed. The unusual care taken in the tightening-up of the flange bolts is no doubt partly responsible for the success attained. I notice on page 1256 a statement that a number of drain pipes were led to a single steam-trap to reduce the cost of traps installed, and, while I favour this arrangement, my object would not have been solely the reduction of cost but rather an endeavour to overcome, as far as possible, a necessary evil. Reference is made to the urgent need of appropriate British Standard Specifications for the higher temperatures and pressures, and it is regrettable that it has been left to private enterprise to develop requirements suited to present conditions.

Mr. A. D. Maclean (*communicated*): The paper is of great value to all engineers on account of the numerous problems which have had to be solved, due partly to the unusual magnitude of the plant involved and partly to the fact that the plant is required for an industrial works where the load conditions are different from those obtaining in central power stations, and where extreme reliability is essential. Not only is the boiler plant as a whole the largest in Great Britain, but the individual boiler units are also the largest, and the remarkable results secured will no doubt encourage the more general adoption of larger units, as is the tendency in other parts of the world. On page 1234 dates indicating the speed with which the various problems were solved and the plant erected, are given. Such rapid progress is evidence of extremely efficient organization, but apart from this such speed could only be made possible by close co-operation between the technical staff of Imperial Chemical Industries and the staffs of the selected contractors. The heaviest burden of the preliminary work must necessarily have fallen upon the shoulders of the authors and their technical assistants, and the energy and ability with which they tackled the problems as they arose call for admiration. The problems governing the lay-out and selection of plant are necessarily different from those in connection with central stations, chiefly owing to the excess of steam requirements over the steam necessary for electric generation only. This factor brings into prominence the question of feed heating, and the authors' solution of the problem is interesting. Central station engineers would not as a rule be in favour of 7-stage feed heating, but from the point of view of an ordinary power station the arrangement is equivalent to 4-stage heating, and the figures given in the paper clearly justify the arrangement adopted. No doubt numerous arrangements were investigated before the selected scheme was finally adopted, but it would be of interest to know whether consideration was given to steam drives for the feed pumps, the exhaust steam being utilized as part of the feed-heating cycle. On the face of it this would appear to enable a somewhat simpler arrangement to be made. With regard to the various automatic controls which have been developed to meet the unusual conditions of operation, the solutions to these difficult problems will be of particular interest to engineers, in connection with other industrial plants where similar problems frequently arise. Mr. Merz has referred to the arrangements made for the accommodation of cables. Whilst I agree with him that in the majority of modern power stations this question has received adequate consideration, I cannot agree that this is always the case. It is certainly not so in the case of most industrial plants, where the cable-runs are usually settled more or less as an afterthought. The importance of this question has become increasingly apparent in recent years on account of the greater concentration of plant in individual power stations and the higher pressures involved; modern practice demands that in laying out a power station as much consideration shall be given to the requirements of cable-runs and outlets from the site for main feeder lines, as to such matters as coal supply and circulating water. In a station with which I was at one time associated the special consideration given to cable-runs resulted in a total absence of cross-overs within the power-station site, and complete phase separation of 33-kV cables within the power house and switch house. The trouble taken to secure this result was thoroughly justified on the scores of cost, freedom from trouble and isolation of faults. The arrangements made by the authors in the way of special cable galleries result in an excellent mechanical lay-out of cables, but there is some doubt as to whether they have not introduced the risk of an extensive shut-down in the event of a serious fault causing a fire in the vertical gallery. It would be interesting to know what provision the authors have made in connection with this hazard. A further paper in 12 months' time, describing the actual operating experience gained on the plant, would be welcome. It is inevitable that a complicated and extensive installation such as this should give rise to some troubles, and a description of these, together with the means adopted to overcome them, would be of great value.

Mr. A. C. Sparks (*communicated*): It is unfortunate that all questions of cost are purposely excluded from the paper, as the general impression given by drawings of the lay-out and certain other features is that the cost per kilowatt and possibly the operating charges would be high. In view of this, I doubt whether the authors' claim that the estimated cost of electrical energy at the busbars is well below the unit cost of any coal-burning station in the world, will be generally accepted without some figures and information as to the basis of the estimate. It would be of interest to know the minimum degree of de-aeration that is considered necessary in the design. Information as to the operation and effectiveness of the de-dusting equipment, the effectiveness and control of the de-superheater to obtain dry saturated steam, the basis of the figures as to the calorific value of the coal (given in Appendix 1) and the analysis of this coal, would also be welcome.

[The authors' reply to this discussion will be published later.]

NORTH-EASTERN CENTRE, AT NEWCASTLE, 24TH MARCH, 1930.

Mr. F. C. Winfield: Apart from the automatic control features, which are largely novel and, I think, mainly peculiar to the special requirements of the Billingham station, there do not appear to be many points to criticize in regard to the electrical arrangements of the station. The lay-out of the switch house appears to have been largely governed by the decision to make the switch bay of the same general dimensions as other bays in the station. This was no doubt done to facilitate quick construction, and the resultant lay-out appears to be quite straightforward. I agree with Mr. Clothier that the main switch chamber should be divided into four physical sections, but keeping the lay-out shown in the paper it would appear that the authors have attempted to divide the main switchgear physically into two sections. The division, however, appears to me to be very incomplete since the longitudinal dividing wall (which, incidentally, is rather weak—being only 4½ in. thick) does not reach to the full height of the chamber. Further, the middle busbar section switch, which constitutes the electrical dividing point between the two halves formed by the wall, is not itself enclosed in a separate chamber. Fire, therefore, in one half-section may affect the isolating devices and busbars connected to this section switch and involve the switchgear in both chambers. I notice that considerable use is made of uncovered steelwork in the main switch chambers. We have had some experience in the past year or two, in a station not very far from Billingham, of the danger of using uncovered steelwork in the event of fire. The position at Billingham seems to be even worse, since, as far as I can judge, the roof of the main switch chamber is made up of steel plates which form the floor of the control cable chamber. A fire in these circumstances might be attended with disastrous results, and I would certainly suggest that some fire protection should be given to this steelwork. The 6 600-volt auxiliary switchgear is also mounted in a single chamber and is relatively closely packed. It is sectioned electrically but not physically and, since this gear is the heart of the station, fire or other serious accident in this chamber would result in complete shut-down. The alternative supply from the Newcastle-upon-Tyne Electric Supply Co. is also brought into the same board, so that this constitutes no safeguard. This is relatively small gear and the fire risk should not be great, but it must always be borne in mind that the human element is indeterminable and that, even with the best switchgear, bad maintenance or breakage of a mechanical part or other accident may result in failure of a circuit breaker with explosion and fire. The authors remark that the cable bridge which carries the outgoing feeders was made necessary by the site conditions. It is my view that in any station in which a very large number of feeders are brought out from the power-station busbars, special provision either in the nature of a cable bridge or a cable tunnel should be provided, as the difficulty of accommodation and maintenance of large numbers of underground cables going in various directions is very great. I should like to know what considerations led to the use of 6·6 kV as the second voltage for auxiliary supplies. Two voltages are clearly necessary for the size of motors with which the authors have to deal, but I should have thought that 3 000 volts would have been more suitable than 6 600 as giving considerably more reliable motors and extending the range of use of this second voltage to motors of much smaller size. I do not think that this would involve any material increase in the cable cost. It is interesting to know that special water-cooling has been applied to many of the motors, and I should be glad if the authors could give some particulars of the arrangement, particularly as regards the supply of water. By the arrangement adopted for running the convertors the Billingham power station is tied to the Newcastle Electric Supply Co.'s system, and later thereby to the "grid," by a link consisting of two 2 000-kW convertors in series. I think that this arrangement will prove troublesome in practice, since any shock on either system will be felt at the link. I agree that so long as protective gear operates satisfactorily there should be no interruption to supplies, but no protective gear is infallible, and, should the reverse-power protection fail, complete shut-down of both convertors appears inevitable. The stand-by protection seems to employ inverse time-limit fuses, which are indiscriminative in the condition being considered, so that this would afford no relief. The special arrangements made in connection with the battery booster are interesting, but in the ordinary type of station operated by supply companies batteries are required for emergency lighting and other purposes besides switch operation, and this generally makes duplicate batteries desirable in any case. The usual practice is to charge one battery whilst using the other, and with such an arrangement these special features are not necessary. I congratulate the authors upon their courage in making such an extended application of automatic control gear. Such gear is practically essential for the load-sharing control, but they have not hesitated to go further than this and employ it almost everywhere.

Mr. A. Howell: The Billingham plant, although an electric power station, has for its primary object the generation of steam for the efficient carrying out of process work, the secondary object being the amount of electrical power which can be generated by that steam in its passage to the process work. The practice of passing steam at high pressure through turbines and exhausting this steam at the correct pressure for use in process or other work is, of course, not new and the main item of interest in the plant in question is the adoption of the high initial pressure and temperature. In a normal power-supply station the amount of boiler plant and generating plant installed are both governed by the electrical load, as the production of electrical power is the initial object. Due, however, to the fact that in the Billingham station the electrical power output is not the primary object, coupled with the necessity for the provision of a plant to supply such a large quantity of boiler-feed make-up water, any direct comparison with a normally designed steam-driven electrical generating station is impossible, and thus there is little in the paper that is controversial. Such controversial points as there are have cautiously been evaded. I refer to the capital cost of the plant and the authors' claim (page 1234) that the estimated cost of electrical energy at the busbars of the station is well below the unit cost of any coal-fired electrical generating station in the world. This claim is not qualified in the printed paper, but I note that when reading the abstract Mr. Humphrey judiciously added a rider to the effect "of any published figures." From an examination of Figs. 1 and 2 it would appear that ample ground space was available. Consequently there was no necessity to economize in the space to be occupied by the plant, and—with the exception of the switch house—the various auxiliaries, etc., in the power plant have been spread out so as to be kept below the first-floor level, rather than built upwards as is the alternative usually forced upon the power station designer when the cost of land is of material consideration. The designers, therefore, appear to have decided upon a standard type of building and have generally spread out the plant details at one level; this has undoubtedly saved a considerable time in planning the station lay-out. It also appears that the cubic capacity of the buildings has not been an important feature in the design, as the retention of the same height of building for each bay of the power plant has been governed by the height demanded by the switch house, this height apparently being adopted in order to keep the roof line at one level. If space had been of importance the feed-heating bay, the pipe bay and the turbine bay could, no doubt, have been reduced, as the cranes appear to be situated well above the height required to handle the largest pieces of apparatus in their respective bays. In the case of the power stations of public supply undertakings matters of this description naturally turn upon the limitation in capital cost commensurate with output, and, although the Billingham plant cannot by reason of its special duties be compared with such stations, it is somewhat disappointing that the authors have been prohibited from disclosing the capital cost. This would have been interesting, as far, at least, as the boiler plant is concerned, for, apart from the high pressure and superheat, which do not materially affect the disposition of plant, there are no extraordinary features in the lay-out. Some of the previous speakers have commented upon the rapidity of erection, and those responsible are to be congratulated upon the short space of time occupied in bringing the plant into being. At the same time, it should be appreciated that a performance of this nature is only a matter of man-hours up to economic saturation point, and of the limit imposed by the cost of construction. These points are unfortunately not referred to, nor is any statement made as to the output capacity of the plant available for giving an external supply to the factory at the end of the 15 months, and therefore no basis of comparison is given upon which to be guided as to the merit of the stated performance. Did the period of 15 months include the preparation of the whole of the working drawings for the fabrication of the steelwork and the civil engineering drawings for the construction of the foundations? Regarding the lay-out of the coal-pulverizing plant, it would be interesting to know why it was decided to install such a large number of mills. Although only 1 280 tons of coal per day are normally burnt in the boilers, the 10 pulverizers are capable of milling 3 240 tons of coal per day. Since the pulverized-fuel bunkers are only large enough to accommodate 6 hours' coal supply to the boilers and the pulverized-coal storage is limited to this period it is not possible to run the whole of the mills together at one time, and thus enable the daily coal requirements to be milled in either one or two shifts. Assuming, therefore, that five mills are running more or less continuously there appears to be 100 per cent of spare milling plant for use in case of breakdowns. It would be interesting if this point were made clear. Has any conclusion yet been come to, on the plant in question, regarding the amount of maintenance and the fineness of the grinding of the roller mills as compared with the ball mills, with the same coal? In present-day designs there is a great demand for maximum natural lighting in buildings, but I imagine that there is an absence of natural light in the pulverizer house due to the provision of a floor at the top of the raw-coal bunkers. This floor precludes the use of roof lighting as regards its utility below the raw-coal bunkers, and the division walls between the pulverizer house and the boiler houses make the building dependent for its direct natural light upon windows in the gable ends. This is not, I imagine, very efficient for a building some 200 ft. long containing a considerable amount of plant, with the result that artificial light probably has to be provided continuously. Again, the provision of a solid floor over the raw-coal bunkers would appear to prevent ventilation of the building via the roof ventilators. The ventilators shown in Fig. 2 seem to be large enough to deal with the cubic capacity of the whole building, and their only use would appear to be to take away the dust as it rises from the raw-coal bunkers during filling operations. At the present time, due to the publicity given to the power generating industry, much attention is being paid to the emission of smoke and grit from power-station chimneys. The paper contains very meagre information upon the important subject of dust removal, but from Mr. Bansall's remarks I gather that the gas velocity through the de-duster of 10 ft. per sec. (mentioned in the paper) has now been reduced to 8 ft. per sec., the efficiency of separation at this speed being 80 to 90 per cent. It would be of interest to know what is the increase in efficiency due to the decrease in gas speed. An efficiency of dust separation of 90 per cent must certainly be a great benefit to the amenities of the neighbourhood, as must also the removal of one-third of the sulphur from the outlet gases. I note that the slurry discharged from the de-dusting plant is fed into a slurry pit along with the boiler ash and thence passed to settling tanks. The easy and cheap handling of slurry from wet washers or de-dusters has presented some difficulty in the past as the dust is so fine that it remains in suspension in the settling tanks for a considerable period, and trouble has been experienced due to fine dust passing away in suspension in the overflow water. It would be interesting to know whether this has been experienced when combining the boiler ash with the slurry from the washer, and whether any special provision was made in the ash-settling pit (such as baffle weirs) so as to ensure the waste water from this pit passing away to the drainage system in a clean condition, thus leaving behind the whole of the dust from the de-duster to be handled by the grab. Regarding the pipework lay-out, the provision of a special building with its attendant crane is a departure from ordinary practice and the size of this building has, no doubt, given the designers ample space for large bends to permit of pipe expansion. The special nature of the plant calls for a considerable amount of piping over and above that of a normal generating station, but economy in space could possibly have been effected by the use of corrugated expansion bends, as these can be manufactured from solid-drawn tubes thick enough for pressures up to 800 lb. per sq. in. Mr. Humphrey's statement that the boiler plant was the world's largest pulverized-fuel-fired plant is apt to be misleading without the qualification of temperature. The maximum output of the 8 boilers of this plant is 2 160 000 lb. of steam per hour. At the State Line generating station at Chicago, U.S.A., which is a separately owned station not possessing its own distribution system but giving only bulk supply, the boiler house contains 6 pulverized-fuel-fired units, each built for an output of 450 000 lb. of steam per hour at 800 lb. pressure. The total output from this plant is therefore 2 700 000 lb. of steam per hour, which is greater than that of the boiler plant described. The temperature at the State Line station is only 756° F., which is 100 deg. F. lower than that of plant under discussion. The question of temperature should therefore be used as a qualification when speaking of this boiler plant as the world's largest pulverized-fuel-fired installation.

Mr. H. W. Clothier also took part in the discussion. The substance of his remarks is included in the discussion before the Institution (see page 1277).

[The authors' reply to this discussion will be published later.]

North Midland Centre, at Leeds, 25th March, 1930.

Mr. G. P. Henzell: The paper is of special interest in that it describes a considerable departure from the usual central station plant. I am interested to know that the designers decided to use mild steel for the superheater after alloy steels had been carefully considered and had been turned down on the grounds of cost and unreliability. I agree that their cost is a disadvantage, but I should like to have some further information regarding their reliability. The superheater itself, as shown on the boiler lay-out, is interleaved between the front bank of boiler tubes, and it seems to me that it would be somewhat difficult to renew a tube without partially dismantling the boiler. I do not altogether approve of the very sharp return bend in the superheater tubes, as this might possibly give trouble due to choking. With regard to the high-pressure steam piping, I think that the designers have acted wisely in adopting very stiff flanges, although I do not agree with them as to the advisability of using screwed-on flanges for such a high temperature. Was consideration given to the loose flange over a stepped-up end? It seems to me also that the jointing material used would eventually soften and possibly blow out as, owing to its thickness, a considerable area is exposed to the high-pressure steam. The steaming economizer is new in practice and I should like to ask whether any trouble due to "water hammer" has been experienced. Is the feed-water regulator placed on the inlet side of the economizer? At Billingham great care has been exercised over the purity of the feed water, and, in this connection, the oxygen content is the only factor that may cause anxiety. It would be interesting to know what the average oxygen-content is, and whether there is any automatic device to take care of it. In describing the high-pressure turbine the authors said that the alternator fan is the only separate auxiliary. This could, of course, have been avoided by driving the fan from the turbine shaft. I do not fully understand the complicated system of automatic control, but I notice that it has been so designed that it automatically goes out of action in the event of failure and leaves the system free for manual operation. I should like to know whether in the working of the impulse system of control any mechanical troubles have been experienced owing to the possible slipping of cogs or ratchets.

Mr. W. Dundas: Among the many interesting features of the plant at Billingham is the adoption of higher initial steam temperatures, without recourse to the use of special materials in the construction of the superheater. It appears that the success obtained is due to the high velocity of the steam through the superheater, as indicated by the unusual pressure-drop of 40 lb. per sq. in., and further comments by the authors on this subject would be of much assistance. The quantity of boiler blow-down (approximately $1\frac{3}{4}$ per cent of the evaporation) is somewhat high. Has a system of continuous blow-down been adopted, or any provision been made for reclaiming the heat lost thereby? The gain in efficiency obtained with the seventh heater appears to be small; have any other factors required in operation determined its adoption? The series arrangement of feed pumps provides a very flexible combination, and particulars of the authors' patented control ensuring stability in operation without the use of surge tanks would be of interest. The type of pipe joint adopted as a result of their experimental investigation is somewhat unexpected and it is a departure from the generally accepted essentials of the metal-to-metal face and welded joint, which has given good results under relatively severe conditions. The adoption of such an elaborate and extensive system of automatic control is a bold step, and one can imagine the effect of a failure on the operation of the plant and the possible consequences and delay in rectifying matters. I should be glad if the authors could give some indication as to the effect of automatic control on the personnel required for operating the plant, expressed in terms of water evaporated.

Mr. T. R. Warren: I think there is little doubt that the Billingham station will influence the design and control not only of future power stations, but also of future power systems, and the paper is particularly opportune coming as it does at a time when the "grid" will shortly be put to the test. The problems arising in connection with the operation of a compounded station such as that at Billingham are hardly less intricate than those encountered in the operation of interconnected systems, but in both cases the governing of the turbines is one of the most important factors to be considered. In America, where interconnection has been carried out perhaps to a greater extent than elsewhere, misapprehension as to certain aspects involved still appears to exist. For example, it is sometimes stated that sensitive governing, by preventing any tendency of the systems to alter in frequency, diminishes load-swinging and so improves stability. At Billingham the opposite view was taken, and it is therefore important to examine more closely the arguments for and against these opposing doctrines. The advocates of sensitive governing lose sight of the fact that the relation between the load on a turbine and its speed is actually the characteristic of the governor itself, and that relatively large changes of load occur in this case with a correspondingly small change in frequency. With coarse governing, however, such changes in load must result from much larger changes in frequency and these latter are, of course, prevented by the inertia of the system itself. In support of this argument it has been found that the addition of oil dashpots to the governor mechanism eliminates load-surging on large systems, and such a measure necessarily produces the same effect as coarsening the action of the governor, when considered over small periods of time, but it is inferior in principle in that it is an unnecessary complication. Intimately bound up with the question of governing is the development of automatic frequency control, an example of which is described in the paper. In America it is now recognized that this form of control, when applied to large systems, possesses merits which cannot be ignored, and several tests have been recently carried out with varying degrees of success. The results obtained over a period of 6 months on the interconnected systems in the Chicago area, which have a normal load of 900 000 kW, are encouraging, but recent attempts to control the frequency of another system on which the load was 200 000 kW were unsuccessful owing, as far as I can see, to incorrect design of the control scheme. As explained on page 1265, when controlling more than one machine automatically it is essential to provide load-sharing means, as this enables sufficient plant to take its share in the duty of frequency control to prevent undue load-changes on any one machine. One of the main advantages of the frequency control applied to the Billingham station is that it enables the governors to be coarsened, and this advantage—as I have attempted to explain—applies to interconnected systems as well. Among the other interesting and novel features described, the automatic electrical operation of the reducing valves at the station is, I think, worthy of note. Valves for this special duty had to comply with three main requirements: (1) They had to be of the non-seated type owing to the difficulty in adjusting the limit switches with great accuracy. (2) Wear of the valve under the combined action of temperature and constant operation had to be avoided. This ruled out the parallel-slide type. (3) The amounts of valve-travel for opening and closing impulses of equal duration had to be identical. The valves consequently had to be of the balanced non-seated type. The usual method of guarding against the sudden failure of a primary machine is to interlock its governor with the corresponding reducing valve, so as to cause the latter to open immediately upon a shut-down of the turbine. Such a drastic procedure as this was unnecessary at Billingham owing to the effect of the large capacity of the process-steam mains in stabilizing the process-steam pressure. With this in mind, it was considered more prudent to allow the automatic steam-pressure control to take care of any emergency which might arise—particularly as this permits of operation upon all three valves simultaneously and so divides the extra duty between them. To cope with wide fluctuations in steam pressure it was arranged that the impulses should occur at a maximum rate of one every 2 seconds, and from calculations this was found to be sufficient to meet all cases.

Mr. R. M. Longman: The electrical switchgear appears to be much the simplest part of the plant. I congratulate the authors on the excellent lay-out which they have achieved under conditions which differ from those generally existing in a power station, namely that the cables are not taken underground. Ample room is provided both for the low-tension and the high-tension cables. Although the space occupied is rather greater than usual it must have paid for itself in the accessibility of all the incoming and outgoing cables. I presume that the cables are lead-covered, armoured and without an external wrapping, so as to reduce any possible risk of fire; perhaps the authors will confirm this. Why was a process voltage of 6 600 adopted, particularly when the existing supply from the Newcastle-upon-Tyne Electric Supply Co. was at 11 000 volts? I think the answer to my question is that the authors wanted as many motors as possible to be run direct at the high voltage without transformation, and they were dubious of using 400-h.p. and 600-h.p. motors at 11 000 volts. As far as the question of motor convertors is concerned, I do not think that there is any need to consider the necessity of using 6 600 instead of 11 000 volts. There are, and have been for many years, a large number of 11 000-volt motor convertors in use in this country under very arduous conditions. The use of armour-clad switchgear is undoubtedly another great asset in this lay-out. With the cubicle or any other type except the armour-clad, the space required for such switchgear would be almost prohibitive. The control apparatus is unusual and represents a great step forward, but I should like to know what sort of frequency graph it gives. Can a fairly steady frequency be maintained? What is the maximum variation, and is the plant run in synchronism with that of the Newcastle Electric Supply Co.? The large amount of power required leads one to consider whether other arrangements of the generating plant which would have give equally satisfactory results in practice could not have been devised. In the lay-out of the electrical equipment (Fig. 22) I noticed the use of reactors, especially tie-bar reactors, with the idea of diminishing the disturbance to the system and of reducing the size of the switchgear required. It would be interesting to know whether they have any real effect and how the interconnection has operated. The generators have 12 per cent reactance so as to bring the total short-circuit current on the busbars to the 500 000 kVA mentioned. The question of the operating staff was mentioned by Mr. Dundas, and I should like to know how many operators are actually required for a plant of this size. Such a large number of valves—I suppose they run into hundreds—must necessitate operators well trained with the plant, if they are to know what to do and where to go. Possibly the apparatus works so smoothly that the valves rarely have to be operated. The large amount of steam required for the process work and the very small amount of condensate water which is returned from it is an unusual feature. Is there no way of reducing this waste of water, because of the water which is required a very large proportion is taken direct and has to be evaporated? I was interested in a description of the de-duster plant by one of the authors, and I feel that they would be right in eliminating the electrical precipitation method although this has many good features, but on the score of cost, space required and reliability they were probably correct in their decision.

Mr. E. A. Logan: In motoring circles the value of racing to the industry in general is sometimes questioned, and the answer is given that the standard models are improved as a result. The Billingham plant might be described as the " sports " model, and there is much in the present paper which will give a lead for future standard models and help to improve power stations in general. I have asked myself the question: Is the Billingham plant a heat-generating station exporting electricity as a by-product, or is it an electrical generating station exporting heat as a by-product? I now realize that neither view is correct, and that in point of fact the title of the paper is the most accurate description which could have been applied. Neither function is subordinate to the other and the plant must properly be regarded as a co-ordinated whole, supplying heat and electricity. Mr. Warren's description of the automatic control gear has made this point clearer. Even realizing that electricity is not a by-product of this plant full credit must be given for the efforts made to secure such a high overall thermal efficiency, the figure of 25·45 per cent quoted on page 1270 being one that even purely electrical stations not concerned with process work can regard as enviable. The question of main cables on a chemically contaminated site has been dealt with in a neat, effective and cheap way. There is another example in this country of a station of much the same rating with contaminated site conditions, but here the problem has been solved by placing the cables in underground tunnels. Except from the point of view of cost, the over-ground method being probably the cheaper, both methods have the great advantage of ease of maintenance. The tunnel method suffers somewhat from the difficulty of dissipating the heat losses, and forced ventilation is necessary at times of heavy load, but on the other hand the cables are screened from the direct rays of the sun. Was any allowance made in the cable rating for the effect of a high temperature due to heat from the sun? I should be pleased to have particulars of the treatment of the cables outside the buildings where, presumably, they are subject to the rather violent corrosive action of the chemically charged atmosphere. Cables supported on bridges, as described by the authors, call for racking, and a controversy is at present raging as to the correct centres of the supporting cleats on which cables are erected. Perhaps the authors may be able to add some information regarding the distance apart of the supporting cleats. I note that certain "draw-out" busbar section-switches are provided in the switchgear lay-out. It appears that some special type of plug-in contact will be required to carry the very large busbar current. I should be glad of information on this point.

Mr. W. L. M. French: I am interested in high-pressure pulverized-fuel installations and regret that the authors do not give more details with regard to their actual operating experiences with this method of firing. Little information is given concerning the class and type of fuel generally being consumed at the station, other than its calorific value of 11 700 B.Th.U. per lb., which suggests that the fuel used is of reasonably good quality. One amongst many of the assets of a pulverized-fuel plant is its claimed ability to utilize low-grade and even waste fuels without seriously reducing commercial steaming efficiency. I should therefore like to have the authors' opinion with regard to the use of low-grade fuels, from a commercial point of view. No information is given in connection with the drying of the fuel. However, an examination of Figs. 2 and 3 reveals the fact that this process is carried out by admitting pre-heated air into the pulverizing mill circuit. This results in very rapid drying of the fuel, but has the great disadvantage that the air must be extracted at a later stage from the mill circuit. What happens to this moisture-laden air? If it is discharged to the atmosphere heat losses and dust-emission will result, yet if it is returned to the furnaces of the boilers the moisture will increase the stack heat-losses and reduce the furnace temperature. When burning small or slack fuel in a stoker-fired plant moistening of the fuel prior to burning becomes an advantage, since it binds the fuel together on the grates and so reduces excess air-losses. It also prevents the smaller particles from being drawn off the grates into the flues in a semi-consumed condition. These advantages are entirely absent from a pulverized-fuel plant. With a fuel containing a given amount of free moisture, theoretically the quantity of heat required to evaporate this moisture should be the same whether it be done by means of some external drying plant or in the furnace itself. From an overall heat-efficiency point of view the latter method would be the better, since serious heat losses occur with most drying apparatus. With pulverized fuel, the extent to which the coal should be dried appears to be determined more by the greater ease with which dry coal can be pulverized. Also, if moisture be present in the pulverized fuel, trouble may be experienced due to clogging of the screw conveyors, arching of the fuel in storage bins, bridging-over in feeder openings, and, above all, intermittent feeding to the burners causing pulsations in the flame. I should like to know what troubles the authors have had in this direction, and what they have found to be the limiting percentage of moisture.

Mr. A. F. Carter: In view of the great complications in a system like the Billingham station, I should be glad if the authors would describe the procedure adopted when starting up the plant. Will they also explain what is likely to happen in the event of a shut-down through the falling out of step of the various machines, and the probable time required in getting back to normal conditions?

Mr. T. Roles: I congratulate the authors, the manufacturers and all who have had anything to do with this plant on the boldness of the design. I am interested to note the extent to which automatic control is used in connection with the plant, as an engineer who has had a good deal to do with the design of the high-pressure plant which is being installed at Bradford has expressed the opinion that too many automatic devices are incorporated in it. I should like to know whether at Billingham the feed pumps are hydraulically balanced, or whether a Michell thrust is used in connection with them in order to take the heavy thrusts which they may have to sustain under working conditions. When high-pressure working was first mooted, a great deal was said as to the difficulty likely to be experienced in connection with valves. It was stated with regard to some early plants that a safety valve had only to blow off once for the seat to be cut up and require replacing. I should be glad to know whether the high-pressure safety valves have blown off on a number of occasions, and, if so, the effect on their seats. I assume that the automatic valves are all electrically, and not hydraulically, operated. Has electric operation been found satisfactory under all circumstances? With regard to the ordinary valves, I notice that parallel-slide valves are used, and as a few years ago it was thought that such valves would not be suitable for high pressure the authors' experience in this connection would be interesting. There has been some controversy as to whether to use the ordinary type of water gauge, fitted with a tube made of some special glass (" Pyrex " glass was at one time said to be very suitable), or whether a gauge made up of flat glass bolted into a frame was better. Perhaps some information regarding the water gauges in use, their length of life and whether much trouble has been experienced in connection with them, could be given. Have the boilers been worked up to full load and overload for a considerable time, and have any ill-effects been observed in any of their parts, such as the superheater and furnace tubes?

[The authors' reply to this discussion will be published later.]

NORTH-WESTERN CENTRE, AT MANCHESTER, 1ST APRIL, 1930.

Mr. W. S. Burge: The magnitude of the demand for process steam and electric power at these works is such that the usually accepted practice of the automatic pass-out turbine has been departed from, and I consider that the consulting engineer has been well advised to divide between different classes of prime movers the duties of base load supply, peak load supply and feed heating, because by so doing he has eliminated as far as is humanly possible all chance of failure of supply and furthermore he has done this with little sacrifice of efficiency. I gather from the paper that pressure control on the process mains and also trimming of the steam supply are in this installation taken care of by the automatic reducing valves, whilst the duty of trimming the electric power demand is taken up by the normal-pressure condensing turbines. The ambitious and necessarily complicated scheme of regenerative feed-heating is isolated from the primary high-pressure units by the provision of separate feed-heating turbines, and thus the primary high-pressure back-pressure turbines are reduced to the simplest possible proportions. One of the greatest difficulties in high-pressure turbine work is to secure a unit of sufficient output to afford a satisfactory blade height through the first few stages of the turbine, and if the output and steam quantity through the high-pressure cylinder happen to prove sufficient for good design these very conditions that make it comparatively easy to deal with the high-pressure section of the machine are a serious embarrassment in the low-pressure section. The primary turbines at Billingham are only rated at 11 900 kW each, but they take some 537 000 lb. of steam on full load. If expanded down to normal vacuum, this amount would yield about 60 000 kW, so that, while these machines work under almost ideal conditions in regard to quantity of steam, the steam is disposed of well before its large volume is able to introduce the usual mechanical difficulties connected with low-pressure expansion. I consider that these primary machines thus have an almost ideal duty. Although the use of automatic reducing valves on a power-station scheme is sometimes considered to be fundamentally wrong from the point of view of efficiency, I do not subscribe to this opinion in circumstances such as those of the plant under discussion. I have little doubt that the loss in thermodynamic heat-drop due to these valves is in normal operation amply balanced by the additional security which they give for continuity of supply in emergency. I should be glad to know whether the reducing valves have yet been called upon to pass the full steam quantity, and if so whether any provision is made for taking the thrust due to energy dissipation. What is their maximum speed of opening? In view of the existence of these valves it has been necessary to install steam de-superheaters; these have a function which is fundamentally wrong—one does not like to burn coal for superheating steam and then to de-superheat it without any thermodynamic gain—but taking all the circumstances into account I fail to see how this could have been avoided without departing from the general engineering policy of the whole scheme. It would be interesting to know whether the de-superheaters are used for the purpose of heating the feed water, because, if so, criticism cannot be levelled at them from the thermal point of view. The use of steam at a total temperature of 856° F. is one of the most outstanding features of the plant, and I hope that this advance will be rewarded with good results. I believe that for many years we have been making bigger advances in high-temperature steam development than any other country, and the credit for this should be given to our long-suffering steel industry. I find that the U.S.A. have lagged behind our own country in regard to the use of high-temperature steam, partly because their boiler plants are forced more than ours and also because their skill as steel makers is inferior to our own. The superheaters are the part of the plant most affected by the combination of high temperature and high pressure, and I presume that the unusually large pressure-drop across the boilers has been deliberately provided with a view to maintaining a high steam speed through the superheater coils for the purpose of cooling the latter. I have found that in the U.S.A. it is becoming standard practice to run radiant and convection superheaters in combination, and also on light loads to limit the steam speed through the superheaters to not less than 2 000 to 1 500 feet per minute. There is also a good deal of controversy as to the best type of steel to use for superheater work, and I believe that experience over there tends to confirm the authors' choice of best quality mild steel. By heating the feed water passed into the economizers up to 401° F. the authors have advanced considerably beyond standard practice, and I am particularly interested in this because I feel that one of the most difficult problems with which power-station engineers are faced at the present time is that of heating their feed water by extraction to the maximum temperature, while still maintaining a minimum terminal temperature at the base of the stack. This problem involves questions of boiler, economizer and air-heater design, and particularly that of furnace design. From data given in the Appendix to the paper it would appear that this plant had realized a feed temperature of 401° F. into the economizer, and a final stack temperature of only 230° F. after the air heater. These two figures are coincident with an air temperature of 500° F. into the furnace, and they give definite proof of very high reception efficiency at the back end of the boiler plant. With pulverized fuel and air heating to 500° F. I should also expect remarkably high combustion efficiency, and I am therefore surprised to find that with definite proof of exceptionally high reception efficiency and strong indications of very high combustion efficiency the overall efficiency of the boiler plant is only given as 81 per cent. I suppose that this figure of 81 per cent is a net value and that it includes the whole of the auxiliary power taken in pulverizing and conveying; this, in my experience, generally accounts for some 3 to 4 per cent of the total amount of coal burned. Have the authors any figures on this subject? In the U.S.A. the heat release per cubic foot of combustion space per hour on most pulverized-fuel systems is now about 18 000 to 20 000 B.Th.U. What is the corresponding rate at Billingham? Information as to the average furnace temperature at economic load and the average ash-fusing temperature would be welcome. I notice that the average evaporation per square foot of heating surface per hour (including the economizer surface) is as high as 17 lb., and this is particularly interesting in view of the fact that only a few years ago 7 to 10 lb. was considered to be a good figure. I consider that this great increase in the evaporation per unit of surface constitutes the chief advance in boiler design, and that the advance is mainly due to pulverized fuel. My experience shows that the chief value of pulverized fuel lies in rating rather than in efficiency.

Mr. K. Baumann: The plant is described as having been laid out on horizontal lines, and this applies not only to the installation as a whole, but also to the individual units. Thus the boilers are not arranged with the economizers and air heaters above the boiler proper, in a way which, I believe, originated in the United States, where in some localities ground space is expensive and economy in this respect is of importance. When using pulverized-fuel boilers, for which a high combustion chamber is necessary in addition, these designs require very high buildings. It would be interesting to know whether the authors have investigated the relative costs of what may be called a "vertical" boiler and the type of boiler which they have adopted. I am interested in the mode of calculating the efficiency of the plant. It judges the commercial value of steam at different pressures not by its heat content, but by the amount of work which it is capable of performing, on the basis of the regenerative or feed-heating cycle. I think that the authors are to be congratulated on having made what may be called a large-scale application of the second law of thermodynamics to power-plant accountancy. A few weeks ago I had an opportunity of advocating the same principle for the purpose of comparing power-station performances on the basis of the regenerative cycle and not—as has been done in the past—on that of the Rankine cycle. I have an impression that some engineers regarded this comparison on the basis of the regenerative principle as rather unjust to some of the existing power stations, and I am therefore glad to find support for my view in the methods adopted by the authors. I note, however, that their calculation of the theoretical power available is based on the adiabatic heat-drop and that it makes an allowance for the steam required for feed heating during actual operation, rather than for the steam which would be required in an ideal regenerative cycle with 100 per cent efficiency. Whilst the difference involved is small, the result is not strictly correct. A chart of the Mollier type is required, although it should not give the heat-drop but what one might term the "Kelvin heat-drop," i.e. the theoretical power available in an ideal regenerative steam cycle. A few weeks ago we were proud to announce that in this neighbourhood a boiler efficiency of 80 per cent and a net engine-room efficiency of over 30 per cent had been obtained. The figures given in Table 3 for the boiler-plant efficiency and for the engine-room efficiency are 34·6 and 70 per cent respectively. This may be the result of the method of accountancy adopted by the authors, but I should prefer to consider the boiler plant purely as a heat-transmitting apparatus. The authors have assigned the cycle value to the steam at the boilers. I suggest that it would be better to give the boiler-plant efficiency in the usual way, and to debit the engine-room efficiency with the shortcomings of the second law of thermodynamics. The lay-out of the steam pipes may appear complicated at first sight, but one must remember that such pipes should be laid out with due regard for flexibility. I think that this has been fully realized by the authors, and their object is certainly attained in the lay-out shown in Fig. 17. The pipe flange which has been adopted is of interest. A similar type, i.e. the screwed flange, has been used in the high-pressure installation at Mannheim, where the steam pressure is 100 atmospheres (1 420 lb. per sq. in.) and the temperature is of the same order as at Billingham. The Mannheim flange was attached by welding on the steam pipe at the back of the flange—a design which I do not consider to be so good as that adopted at Billingham. It has been reported that difficulties due to steam leakage have been experienced at Mannheim, and it would be interesting to hear whether the authors have had similar trouble. The bolt stresses at Mannheim are considerably higher than those at Billingham. The creep strength of steel is not as high as, a few years ago, we thought it to be, and I therefore consider the adoption of low bolt stresses at Billingham to be good practice. With regard to the estimated or anticipated steam consumptions (Table 8), the primary turbines have been tested at the makers' works with reduced loads but under the full heat-drop conditions, and, although the results are not yet available for publication, I may say that this turbine is considerably more efficient than is stated in the paper. I hope in the near future to have an opportunity of giving further information with regard to the design and performance of this primary turbine.

[The authors' reply to this discussion will be published later.]

TEES-SIDE SUB-CENTRE, AT MIDDLESBROUGH, 2ND APRIL, 1930.

Mr. R. J. Huntley: The plant must appear to many to be complex, but we found to our relief that as it settled down to steady running it became relatively simple to handle. A first impression was that the machines were spread over an unusually large area, but later experience made one realize that the plant could not have been more compactly placed without being made unmanageable. A more compact arrangement could have been obtained by coupling mechanically on one shaft a primary turbine, a feed-heating turbine and a condensing turbine, but this would have sacrificed a flexibility in the plant which is invaluable for efficient running. It must be remembered that, in addition to 80 000 kW of generating plant, the building contains feed pumps and feed heaters capable of handling a water quantity equivalent to an electrical capacity of about 200 000 kW, and a distillation plant that would be sufficient to meet the normal make-up requirements of a power station of about $1\frac{1}{2}$ million kW capacity. Therefore this feed-water plant could not have been hidden away under the turbine floor, or squeezed between the turbines and the boiler-house wall, as in stations of more normal design. We who operate the plant are specially glad that economic considerations permitted the designers to lay out a steam-control floor in the pipe bay, for in times of trouble it has meant that one man has been able to control the whole of the turbine floor from this point, and to have operated half-a-dozen main steam valves at the same time, rapidly and without fear of mistakes. The provision of four steam lines supplying a primary turbine, and four exhaust 275 lb. per sq. in. lines, has proved an advantage; full load can be maintained on only three lines and 10 000 kW on two, thus making it possible to carry out maintenance work on steam ranges without undue difficulty. The primary turbines are running absolutely reliably, and are the simplest turbines in the station to put on load. About 4 hours are usually taken to bring the steam lines up to pressure, about 2 hours to warm up the turbine, and in the neighbourhood of $\frac{1}{4}$ hour to run the turbine up to speed from standing. Recently one of them was warmed up and put on load in $\frac{3}{4}$ hour. The turbine is warmed up on a bypass exhaust valve from the 275 lb. per sq. in. mains; when up to pressure the exhaust valves are opened, and the turbine is run up on two $2\frac{1}{2}$-in. bypass valves to about 1 800 r.p.m., when it is necessary to crack a main stop-valve to reach full speed. The main reducing valves used for bypassing the primary turbines showed no signs of wear or scoring on the valve faces when opened up for inspection 2 or 3 months ago, although they had been in continuous service for from 6 to 9 months. Certain fundamental points about the plant have always to be remembered. The exhaust pressure of the primary turbines must always be held at 275 lb. per sq. in.; the maximum load that can be put on a primary turbine at any time depends on the steam flow through the station; and the maximum load that the feed-heating turbines can carry is governed by the feed-water flow, that is to say, by the steam flow. It is seen, therefore, that a complete cessation in steam demand by the process plants reduces the total generating capacity of the station to about 28 000 kW, the load being carried on the two condensing turbo-alternators and one feed-heating turbine. It is interesting to know that the automatic pressure and frequency controls on the turbines work satisfactorily. I must admit that I have been converted from complete scepticism to a belief that this apparatus is worth while. It is yet too soon to say that it is completely satisfactory. Time alone will prove its reliability, and experience only will show how it handles sudden changes of steam and electric load of large magnitude. Sudden reduction in the boiler-house steaming rate, occasioned, say, by the loss of a boiler, may necessitate going over to hand control and allowing the constant 275 lb. per sq. in. steam pressure to fall and so ease the steam demand on the high-pressure boilers and throw an overload on the 275 lb. per sq. in. boiler house. The automatic pressure-control definitely keeps a steadier 275 lb. per sq. in. pressure than does manual control. The speed regulation of the feed-heating turbines, which are loaded and controlled manually to keep a constant back-pressure, will probably have to be coarsened, for at present it is too sensitive, and changes of electrical load on the station, which should be taken up immediately by the machine on automatic frequency control, affect these machines. It is also of interest to know that it is perfectly practicable to control the steam pressure, station frequency and load distribution on turbines by hand; in fact, the station was run in this manner until quite recently. Therefore the justification of the automatic control in this station is that it is more efficient than manual control and saves operating labour. One feed-heating turbine with its feed heaters and the " B " and " C " feed pumps associated with them form an entity, and the getting-away of one group and transferring to it, step by step, electrical and feed-water load from another group is one of the neatest operations in the station, and one which can be performed without varying the final feed-water temperature by more than two or three degrees. The most vital machines in the plant are the two 6-stage sealing water pumps, delivering cold water under pressure to feed-pump glands, keeping them cool and preventing the hot feed-water reaching the gland packing. A 3-minute shut-down of these pumps is sufficient to cause the feed-pump glands to seize. The incorporation of the No. 2 feed heaters in the distillation plant is ingenious. Actually, the 6 evaporators forming one distillation set are grouped to give two sets, one a quadruple effect—consisting of 4 evaporators—drawing its steam from the turbine and exhausting the vapour from the last effect into the de-aerator which acts as the first stage feed-heater, and one a double effect—consisting of two evaporators—ing its steam from the same source and exhausting the vapour to the second stage—or No. 2—heater. I would ask the authors why they provided each feed heater with an extraction pump to extract the condensed steam and add it to the feed-water range immediately after its heater, instead of allowing the condensate to drain to the previous stage heater and flash off a certain amount of steam before draining to the next lower stage, the condensate from all the heaters finally entering the de-aerator heater at a low temperature. For a given size of heater, their method is more efficient in that they use smaller quantities of higher-grade steam and larger quantities of lower-grade steam than would be the case in the cascade drain arrangement, but it seems to me that the same efficiency could be obtained by increasing the heater heating surface, even though this increase would have to be very considerable at the lower stages. Cascade draining would, of course, entail an increase of the capacity of the " B " and " C " feed pumps to that of the " A " pumps. The economic balance thus weighs the increase of size of heaters and feed pumps, coupled with decreased operating, labour and maintenance costs, against the employment of 19 separate heater extraction pumps.

[The authors' reply to this discussion will be published later.]

SCOTTISH CENTRE, AT GLASGOW, 8TH APRIL, 1930.

Mr. N. C. Bridge: The authors remark that the conditions governing the design of the plant described differ essentially from those relating to a public supply station. In my view there are two, and really only two, fundamental differences, and these are so exceptional that they might well be further emphasized in their bearing on the general conception of the plant. I refer to the 100 per cent load factor and the 40 per cent make-up feed. The process steam requirement has scarcely the same bearing as the foregoing factors, since what is done to meet this is analogous, apart from the relative capacity of the condensing turbines, to what has to be done in pressure-compounding an existing station. The same considerations arise in regard to the initial steam conditions, and the same inherent complications as regards emergency provisions for pressure reduction and de-superheating. There is undoubtedly, however, a good deal more justification for the compounding arrangement in the case of Billingham than in the case of any public supply station. The authors mention continuity of supply as being a primary condition, but this is equally the aim in public supply stations, upon which not one, but usually a number, of important industries depend for continuity of operation. The load factor on the Billingham plant must be the envy of public supply undertakings, and it is only this factor, I think, that saves the whole design from condemnation as decidedly extravagant in its conception and in the elaboration of auxiliary equipment and automatic controls. The authors claim that the estimated unit cost of power is lower than that of any other coal station in the world, but this statement is not very helpful, since no indication is given as to how the charges are assessed as between power generation and process steam, and it is not even made clear as to whether capital charges as well as operating costs are included. As regards the proportion of make-up feed water required, the position is entirely different. The separate feed-heating turbine exhausting to an evaporating and de-aerating plant is undoubtedly the proper means of dealing with this particular need, though this again introduces complications which would be quite inexcusable in a normal plant with 4 per cent or so of make-up. The question of maintaining the output from an evaporator, where river water is used for the raw feed, is one that must claim increasing attention in view of the total ban on undistilled make-up necessitated with high-pressure boiler plant. Some form of chemical treatment to reduce the rate of scale formation on the evaporator tubes would appear to be essential if " outage " and cleaning costs are to be kept within reasonable limits, and it is quite understandable that this question, in the case of the Billingham plant, would assume a perplexing importance. There is, however, only a very brief reference to the matter in the paper, in the last paragraph under the heading "Distillation" on page 1261. The introduction of phosphate appears to be of some value in throwing down the hard salts as sludge instead of allowing them to adhere as scale, but, as often happens, the remedy gives rise to a fresh problem. Priming takes place and a proportion of the salts are carried over with the vapour in suspension. This, at any rate, is what is happening in a case that has just come to my notice, and we are now trying to find a remedy for the priming. Perhaps the authors from their extensive experience will deal a little more fully in their reply with this question of the pre-treatment of raw water. As regards the steam-water cycle adopted at Billingham, one rather hesitates to criticize a scheme which is so obviously the outcome of the most careful thought and expert advice, but some explanation seems desirable as to the justification for the seventh stage feed-heater. This heater is shown to require live steam of a potential value of nearly 10 000 kW, and the only reason given for its adoption is to permit of the accurate adjustment of the final feed temperature. What is there about the boiler plant that needs this extraordinary sacrifice of energy to obtain such precision with the feed temperature? The increased gain in thermal efficiency due to the last heater does not appear to be more than about 0·25 per cent and it would, I think, have been much simpler to have increased the capacity of the economizer. The final boiler feed-pumps would certainly have been less troublesome to design in this case. In endeavouring to adjust the authors' thermal efficiency calculations to a further case with only six heaters, I have noticed a discrepancy, as between Appendix 1 and Appendix 2 (Case 4), in the figures for the steam and water heat values for the adopted conditions. The figures in Appendix 2 seem to be incorrect in this respect, though the resultant figure given for steam generated appears to be correct.

[The authors' reply to this discussion will be published later.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 14TH APRIL, 1930.

Dr. C. C. Garrard: It is particularly appropriate that this valuable paper should be sponsored by Imperial Chemical Industries, Ltd., as it is to the chemical industry, I believe, that we must look for any real advance in the methods of generating power. Watt invented practically everything in connection with the steam engine 150 years ago. I do not know the thermal efficiency of Watt's engine, but the authors obtain a thermal efficiency of 24·22 per cent (see page 1270). At this rate of progress it would require, say, 450 years yet before we approach, in steam power generation, the efficiencies to which electrical engineers are accustomed with their machines. But this, of course, is only a fantastic suggestion because with steam power generation, as at present understood, we approach asymptotically to a theoretical upper limit of thermal efficiency, which in any case is nowhere near the efficiencies obtained, as I have said, with electrical machines. I feel convinced, however, that before long the chemical engineer will revolutionize the generation of power and thereby eliminate what are, after all, the present wasteful methods. The authors claim a cost of generation of electric power well below the unit cost of any electric generating station in the world depending on coal as a fuel. The thermal efficiency of 24·22 per cent is, however, exceeded by several modern power stations. In addition, it must be remembered that the load factor of any public supply generating station is lower than that of Billingham. For example, the Philadelphia Power Co. reported several years ago that the overall thermal efficiency of their Richmond station was 24·7 per cent at a load factor of 54 per cent. I believe I am correct in saying that at the present moment there is in course of construction an electric supply station which will have an overall efficiency of 27 to 28 per cent, and that with less extreme steam conditions than those mentioned in this paper. It follows, I take it, that the low cost of production obtained by the authors is due in great part to the high load factor (close on 100 per cent) and the low price of fuel. It would be interesting if the prohibition of publication of cost figures could be relaxed to let us know this latter figure. The design of the whole plant seems to me to constitute a great triumph for the principle of automatic control. There is no doubt that for routine duties a machine is more reliable than a man. I am not quite clear about the impulse generator (Fig. 23). On the shaft of this there appear to be 4 discs. I take it that 1, 2, 4 or 8 impulses are generated per revolution of the shaft. If so, this would seem not quite to agree with the description given at the foot of column 2 of page 1266. Why was this method of impulsing for pressure control adopted? I can understand such a scheme for frequency control as it is the natural thing to do, viz. to operate by impulses depending upon the difference between the actual frequency and the standard clock frequency. Was the arrangement used for pressure control simply to make it similar to the frequency-control method? It seems to me that it would be simpler to regulate the whole operation by the pressure relay itself, one contact being made when the pressure is too high and the other when it is too low. My difficulty in understanding why this impulse method for pressure control is necessary would doubtless be obviated if it were explained how the contactors or relays which receive the impulses respond to such impulses. I assume that with a high speed of impulses the valves are opened and closed more quickly than with a low speed of impulses. If this be so are hunting troubles thereby entirely prevented? Possibly the impulse method for pressure control is more free from such troubles than the simpler method.

Mr. W. A. Barnett (*communicated*): I should like to ask why the boiler blow-down loss appears to be so high, viz. 18 400 lb. per hour, approximately 1·7 per cent of total evaporation and 5·8 per cent of total raw water supplied, considering the fact that the water goes through a good distillation process. Does this figure include blow-down from all parts of the plant, evaporators, etc.? Are any chemicals used to preserve slight alkalinity in the system, thereby causing concentration in the boilers? Although the oxygen content of the actual boiler feed is low, has any internal corrosion of the steel economizer or boiler tubes been experienced? There is no mention of automatic combustion control. Would not this have somewhat improved the boiler efficiency and operation? As simplicity is a factor which needs consideration from the points of view of operation, safety, and continuity of service, the complications of the system caused by live and bled steam feed-heating seem to be great when the slight increase in efficiency is considered. I should be glad if the authors would say why a frequency of 40 cycles was adopted, in view of the fact that 50 cycles is the standard throughout the country.

Mr. R. H. Rawll (*communicated*): It seems that three motor-convertor sets are utilized to provide the d.c. supply for the more important auxiliary drives. One of these sets runs "floating" on the supply company's mains on account of it being considered essential that an alternative supply for the d.c. auxiliary drives should always be available. Great care seems to have been exercised in the design of the whole steam and electric plant to provide duplicate units, and yet this stand-by motor-convertor is not duplicated. I can understand that if this particular set remained stationary until it was required for use in an emergency, its duplication would not be justified on economical grounds, but since it is always running, whether required or not, a fault developing on it might put it out of commission just at the time when it was required for stand-by purposes. I assume from the paper that one of these motor-convertor sets is always run from the supply company's mains. If, of course, each of the three convertor sets can be run either off the station busbars or the supply company's mains, the above criticism does not apply. I should therefore be glad to be enlightened on this point. It is also stated in the paper that the auxiliary d.c. supply is at 460/230 volts, 3-wire, the neutral being earthed. This supply at 230 volts, of course, provides the energy for switch operation, etc. I presume that all control switches are of the double-pole type, because otherwise an earth on a control circuit might inadvertently operate the switch, etc., to which it is connected.

[The authors' reply to this discussion will be published later.]

THE SERRA HYDRO-ELECTRIC DEVELOPMENT, SÃO PAULO, BRAZIL (WITH SPECIAL REFERENCE TO THE ELECTRICAL LAY-OUT).

By R. W. H. COUZENS, M.A., Associate Member.

(*Paper first received* 29*th October*, 1927, *and in final form* 2*nd September*, 1929; *read before the* EAST MIDLAND SUB-CENTRE 25*th March*, 1930.)

SUMMARY.

The paper is a general description of the hydro-electric development at the Serra de Cubatão, in the State of São Paulo, Brazil. The general load and climatic conditions which led to the development are outlined, together with the advantages of the site chosen for the power house and reservoirs. The method of the provision of power for constructional purposes is next described.

There follow details of the permanent lay-out and the construction of the power house and its equipment. The switch-house lay-out and equipment, and the control and relay systems are described. Details of the earthing system, the 88 000-volt outdoor equipment, the transmission line and the São Caetano terminal station for the city of São Paulo are set forth.

Finally, the capacity and cost of the development and the São Paulo system are dealt with.

GENERAL.

In 1924 it was estimated that about 1 per cent of the potential water power in South America was developed. Brazil is one of its richest countries as regards water power, largely owing to the fact that over a considerable proportion of the coast-line the land is a well-watered plateau dropping steeply near to the coast. As elsewhere, however, the largest waterfalls are at a great distance from industrial activity.

The city of São Paulo has grown exceedingly rapidly as regards population and electrical load; so that, while in 1900 only 1 000 h.p. was installed and there was no storage reservoir, by 1910 a total of 27 000 h.p. was installed and 7½ million kWh of storage capacity was available. In 1916 the peak load was 25 000 kW and the storage capacity had increased to 110 million kWh; and 10 years later, in 1926, the peak load was 59 000 kW, with 148 000 h.p. installed and a storage capacity of 120 million kWh. In June 1929 the peak load was 88 600 kW and the storage capacity 238 million kWh.

In the middle of 1925 the following plants were supplying power: Parnahyba, with a capacity of 18 000 kVA, at a distance of 14 miles from the terminal station; Sorocaba, with a capacity of 58 000 kVA, at a distance of 48 miles from the terminal station; and a reserve steam plant in the city, with a capacity of 10 000 kVA.

It will thus be seen that the capacity of the plant installed is in all cases greatly in excess of the peak load to be carried, since certain plants are dependent on river flow and are used in flood season to full capacity, while others, with ample storage, store the flood-water and operate at full capacity during the dry season. The cycle of weather appears to cover a period of 10 or 11 years, which include two dry years with an intervening season of scanty rain which is insufficient to refill the reservoirs. Such a season occurred in 1924–5, and rendered necessary the erection of a power plant of two 14 000-h.p. units at Rasgão, on the River Tieté, below Parnahyba; this plant was in operation within 12 months of the decision to erect it. It was also decided to construct with all possible speed a plant at the Serra de Cubatão—a project which had previously been studied and decided on, delays, however, occurring in the acquisition of land and rights.

The construction of this plant was begun in March, 1925; the first unit was in operation in October, 1926, and the second in April, 1927.

POWER-HOUSE SITE.

The site of the Serra penstocks and power house is a spur on the edge of the rolling plateau which follows the coast but slopes gently inland. The site is distant only 22 miles from São Paulo and 10 miles from the port of Santos, whence railway transport is available direct to the power house itself.

The prevailing winds are south-east from the Atlantic Ocean, and these precipitate their moisture on reaching the plateau, causing on its edge a very high average rainfall, which decreases rapidly further inland. The rainfall at the Alto da Serra—the top of the pipe-line—is probably 173 to 264 in. (4·4 to 6·7 m) per annum, averaging about 197 in. (5 m). No accurate data at this particular place were available before construction began, but since then the fall has been greater than at the Alto da Serra on the São Paulo Railway, some 10 miles distant to the north, where it averages about 150 in. (3·8 m).

On the plateau rise a number of small tributaries of the Tieté River, whose normal course to the Atlantic Ocean is over 2 000 miles; and the small difference in elevation in the valleys enables large reservoirs to be formed by relatively low dykes and so provides storage for the flood-waters of these streams.

RESERVOIRS.

An effective storage capacity of 37 771 million cub. ft. (1 070 million m^3) is obtainable; the reservoirs proposed are shown in Fig. 1. The Rio das Pedras reservoir nearest to the power house has a maximum water-level of 2 384 ft. (727 m) and a surface area of 2·7 sq. miles (7 km^2). It is formed by a concrete dam of arch and gravity section, about 99 ft. (30 m) high, which closes the gorge at the point where the Rio das

Pedras had cut its way through the crest of the plateau. This affords a spill-way for flood-waters; and further to the east, by a dredged connection and control works, the valley of the Perequê serves as an additional spill-way.

The Rio das Pedras reservoir is connected to the Rio Grande reservoir to the north-west by the Summit Canal which, including the portion within the two reservoirs, is 10 miles (16 km) in length. The Rio Grande reservoir has an ultimate water-level of 2 442 ft. (745 m) and a surface area of 53 sq. miles (137 km^2). There will thus be a difference in level between the Rio Grande and the Rio das Pedras reservoirs of from 10 to 60 ft. (3 to 18 m) available for power production in a power station of 18 900 h.p. capacity at the Summit Control. The Rio Grande dam forms the main storage reservoir to the north-west, and north-westwards from this point the river is being dredged and straightened to form a canal to connect with the Tieté River, on which the Parnahyba and Rasgão power stations of the company are situated. These power plants on the lower Tieté were originally served by the storage reservoir at Santo Amaro, with a surface area of 13 sq. miles (34 km^2) and containing 6 869 million cub. ft. (194 600 000 m^3) at an elevation of 2 416 ft. (736·6 m). The City of São Paulo is at present drawing 35·3 cub. ft. (1 m^3) of water per sec. and later will draw 141·2 cub. ft. (4 m^3) per sec. from this last reservoir to supplement the city water supply.

By installing pumps of a capacity of 5 295 cub. ft. (150 m^3) per sec. at the Marumby and Rio Grande dams it will be possible to divert surplus and flood-water from the Tieté and its tributaries to the Rio Grande and then through the Summit Control to the Rio das Pedras reservoir, and thus, by the expenditure of the energy necessary to pump the water up 115 ft. (35 m), to obtain the advantage of a total head of some 2 400 ft. (732 m), at the same time relieving the low-lying portions of the city, which are badly flooded after long rains. The pumping operations can usually be performed at night and on holidays and generally at times of low load, but in the flood season, when much surplus power is available from other plants, they will operate continuously.

The total flow, regulated by the storage of the above-mentioned reservoirs and the others shown in Fig. 1, is sufficient for a total capacity of over 400 000 kW. The existing two units have a capacity of 33 000 kVA each, and it is planned that further units each of 48 000 kW capacity shall be installed as and when required by the growth of load. The third unit has already been purchased and will be in operation during 1931.

The formation of these reservoirs necessitated five road alterations on the main São Paulo–Santos highway, the largest of which is by the village of Rio Grande, where the road has to be raised 49 ft. (15 m), for which purpose a reinforced-concrete bridge 263 ft. (80 m) long and an embankment 1 094 yds. (1 km) long, requiring 654 000 cub. yds. (500 000 m^3) of material, are being constructed.

The chain of reservoirs and canals will connect the edge of the Serra with the City of São Paulo. The company has legislative authority to connect the city with the port of Santos by lighters and an aerial rope-way from Santos to the top of the Serra, or by means of a boat incline up the slope of the Serra and suitable boat-lifts and locks at the Summit Control and the Rio Grande and Marumby dams, thus relieving the congestion at the port. Detailed studies are still in progress and no final decision as to this part of the project has yet been reached.

General Construction and Lay-Out.

For constructional purposes a camp was established at the power-house site for the erection of the power house and penstocks, since all the material arrived by rail from Santos. A second camp was established at the Alto da Serra for the construction of the dam, the tunnel, the siphon and the surge tank. A third camp, detached from the remainder by about 9 miles (14 km), was established to cut the Summit Canal with a 12-in. and a 10-in. suction dredge to join the Pedras basin with the basin of the Rio Pequeno. In order to provide power for constructional purposes in a time of great shortage, it was proposed to build three temporary plants, each of 900 kVA capacity, with about 656 ft. (200 m) head, down the original falls of the Rio das Pedras. However, owing to the lack of labour and the cessation of the power shortage one only was built and was operated in parallel with a line from the City of Santos Improvements Co.'s supply. Later, after the permanent transmission line had been completed, the load was carried on a 40 000-volt circuit from São Paulo. The power house was a temporary wood-and-masonry structure with a galvanized-iron roof. The unit was a 1 200-h.p. impulse turbine manufactured by the Hilpert Co., of Rio de Janeiro, coupled to a 900-kVA generator formerly in use at Rio de Janeiro; a turbine-driven and a motor-driven exciter were also provided. This plant generated and transmitted at 3 800 volts. A construction substation was located in the main power-house camp about a mile from the temporary power house, and here a 3 000-kVA transformer bank with a ratio of 13 000/3 800 volts and a tertiary winding for 6 600 volts was provided. The 13 000-volt winding provided the parallel connection with the Santos supply and also fed the two suction dredges working on the canal connecting the reservoirs some 9 miles (14 km) from the power house; while the 6 600-volt service supplied power for the hoists, compressors, rock-crushing plants and derricks at the upper camp, the 3 800-volt supply being used around the power house for supplying compressed air for the pipe line, crushing plants, derricks, ice plant and other necessary equipment.

Hydraulic Works.

From the Rio das Pedras reservoir the water is conducted through a short cut 984 ft. (300 m) in length into the Cascatinha ravine, closed by two earth-filled dams with concrete-core walls, and, from this branch of the reservoir, through a tunnel 1 608 ft. (490 m) long and 10·6 ft. (3·25 m) in diameter lined with concrete and capable of supplying water for four units. A second tunnel was driven for a distance of about 164 ft. (50 m) from the intake in order to avoid risk of damage to the intake works which might be caused by blasting in construction at a later date. Four tunnels ultimately are planned. There is a sand trap in front of the tunnel

FIG. 1.—São Paulo and District transmission system and reservoirs (existing and proposed).

intake, and trash racks to be provided with stop logs with hoisting gear and, later, with electrically-driven automatically-operated rack-cleaners.

An inverted siphon of steel, 427 ft. (131 m) long and 8·21 ft. (2·5 m) in diameter, crosses a ravine 98·5 ft. (30 m) in depth from the tunnel to the surge tank hill and enters the surge tank. The siphon is to be enlarged at a later date and constructed of reinforced concrete. There is an anchor-block at the bottom of the siphon, with a sand trap and large blow-off valve.

The surge tank is of reinforced concrete and its top is 2 426 ft. (739·5 m) above sea-level. The top of the superstructure is 2 510 ft. (765·2 m) above sea-level, the nozzle of the turbines below being 30·4 ft. (9·26 m) and the tail-race, in the old bed of the Rio das Pedras, 13 to 20 ft. (4 to 6 m) above sea-level. Arrangements have been made for four pipe lines in the present surge tank, only two having been installed at present. Stop logs with hoisting gear are provided at the outlet.

PENSTOCKS.

The high-pressure pipe lines were manufactured by the Ferrum Co., of Poland. The internal diameter of the pipes is 5 ft. (1·55 m) at the top, reducing in three stages to 3·6 ft. (1·1 m) at the bottom. The two penstocks are secured by 15 concrete anchors weighing from 1 200 to 5 000 tons each, the soil being decomposed rock. An expansion joint is provided between each pair of anchor-piers, and saddles are placed under the pipes at approximately 33 ft. (10 m) spacing, and at an elevation of 2 083 ft. (635 m) the penstocks are carried through two concrete-lined tunnels under the main São Paulo–Santos highway.

The minimum thickness of the pipe is 0·394 in. (10 mm) and the maximum thickness of plain pipe at the ninth anchor-pier is 1·261 in. (32 m); below this, 24 heavy bands of seamless high-carbon steel are shrunk on to each section of the pipe, the thickness of the pipe being 0·946 in. (24 mm) and the bands averaging 4 in. (100 mm) long and 1·892 (48 mm) thick. The total weight of each pipe line is approximately 1 600 tons; the maximum gradient on the line is 86 in 100 and the maximum velocity of water in the pipe is 264·75 cub. ft. per sec. (7·5 m^3 per sec.). A spare pipe of each size is provided, and the spare pipes are located on the top of the anchor-piers.

The company is conducting an extensive series of tests on test pipes, which are designed on the assumption of safety even under the worst possible condition, namely the fracture of the needle spindle of the nozzle of one wheel determining the stresses which may be set up in the various sections of the pipe.

At the top of each penstock are the usual screens and gate, and in the valve house, 49·25 ft. (15 m) from the surge tank, an air vent-pipe is carried up to the height of the surge tank. Above this is a butterfly valve 5 ft. (1·55 m) in diameter with an automatic paddle trip and a solenoid trip. The latter is in two halves, which are operated by two distinct circuits from the 250-volt control battery in the power house, the one running in rubber-insulated lead-covered cable in conduit between the penstocks from the power house to the valve house, the other running in rubber-insulated lead-covered and armoured cable laid in the soil by a circuitous route keeping on the far side of a fold in the hill so as to be out of danger in the event of a slide or an accident to the penstocks. These circuits are operated by two push-buttons connected in parallel, each push-button operating both circuits and a lamp to indicate flow of current. One set of push-buttons is on the main control desk in the power house and the other beside the corresponding unit in each case.

A recording and indicating Venturi meter is installed just below the first anchor-pier; and in the fifteenth anchor-pier at the entrance to the power house a Y-piece divides the water for use in the two wheels which form one unit. At the bottom of each penstock are the hydraulically-operated electrically-controlled gate-valves of the turbines.

POWER HOUSE.

General constructional features.—The entire framework of the power house is composed of reinforced, graded concrete which, by suitably proportioning rock of different sizes, reduces voids to a practical minimum, and so obtains a greater strength, corresponding to the higher cement/water ratio, with the use of less cement, care being taken that there is sufficient of the intermediate and finer sizes to permit of its being placed without excessive labour or bad work.

The main columns are 3·28 × 3·94 ft. (1 × 1·2 m) in section, spaced at 14·76 ft. (4·5 m), 44·28 ft. (13·5 m) being required for each unit, the breadth of the power house between inside faces of columns being 51·66 ft. (15·75 m).

Two travelling cranes each of 90 tons capacity are installed, the height of the crane beam being determined by the clearance of 39 ft. (12 m) required for lowering the generator rotor sections on to the shaft. Roof trusses of steel support a reinforced-concrete roof which is covered with asphalt.

On the main generator floor, at an elevation of 32·8 ft. (10 m), are located the main units, governors, governor oil pumps, pressure receivers, air compressors, film oil pumps, exciters and generator field control panels.

Below this, at an elevation of 20 ft. (6 m), are the flood lubricating-oil system pumps, filters, sump pumps (a.c. and d.c.) and pumps for emergency water supply for cooling bearings and transformers, pumping water from the tail-race to a tank on anchor-pier No. 14 and controlled by float-switches in the tank. There is also a high-pressure bus pipe for the operation of the exciter turbines from any penstock.

The present lay-out in the power house, consisting of two units, two exciters and a spare exciter with auxiliaries, may be briefly described as follows:—

Turbines.—The main turbine units were manufactured by the Pelton Co., of San Francisco. Each has two runners overhung from two horizontal bearings, and is of the impulse type with a guaranteed full-load horse-power of 40 000 at a net head of 2 230 ft. (680 m), a static head of 2 345 ft. (716 m), and a speed of 360 r.p.m.; the runaway speed is approximately 85 per cent in excess of normal, and the flywheel effect of the generator is 3 million lb.-ft.². The bearings are 24 inches in diameter and 72 in. long; 8 oil rings are provided for automatic lubrication, and an indicating thermometer indicates the temperature at either end of each bearing barrel. Copper tubes provide a circulation of water for oil cooling in the bearing pedestals. A high-pressure pump introduces oil at 250 lb. per sq. in. under the shaft in the bearing so as to float it on a film before starting up the unit. Flood lubrication is provided, and protection against interruption is secured by oil tanks on the roof to be used in emergency.

The buckets, of cast steel, are of the modern Pelton type, fastened by pressed-on bolts to the rims of disc wheels which in turn are pressed on to the ends of the shaft. The main needle and a relief needle immediately beneath it are mechanically linked through a dashpot mechanism which determines the closing time of the relief nozzle after it opens on closure of the main nozzle. A stream baffle-plate of cast iron fitted with a renewable splitter of cast steel receives the discharge of both nozzles, and is supported on **I**-beams and rigidly embedded in concrete. A braking nozzle is provided on each wheel, directing a jet on to the backs of the buckets to stop the unit. The nickel-steel hollow shaft carrying the generator and turbine rotors is 30 ft. in length and has a maximum diameter of 30 in.

Generators.—The generators were supplied by the International General Electric Co., and each has a maximum continuous capacity of 33 000 kVA at 0·85 power factor with a normal voltage of 11 000 and a possible over-voltage of 5 per cent at full load. The excitation is 250 volts maximum, using 105 kW at maximum load. The rotor spider is composed of four main sections of rolled steel punchings approximately ¼ in. thick, these sections being shrunk on to the shaft in the field. The field poles are each secured to the rim by two T-shaped dove-tails, four taper keys being used for each T to lock the poles in place. The stator frame is in two pieces, the necessary coils for joining the split in the field being shipped separately. Six embedded temperature coils of the resistance type register slot temperatures on an indicator dial in the control room.

The ventilation of the generators is effected by fans on the rotors. These suck air from the power house and discharge it through air ducts to the back of the switch house. In order to prevent the entry of insects, the rolling doors to the transformer platforms are supplemented by galvanized mesh-screen doors. A small flow of the hot air from the air ducts is used for drying lockers in the operators' changing room, and doors are provided for diverting the hot air into the remainder of the power-house basement, thereby keeping dry the motors of the oil and sump pumps and any generators which are shut down.

Fire protection is provided for by means of perforated piping inside the end-shields of the stators, controlled by valves in a metal case on the stator frame. This is intended to be used in emergency to spray water on to the windings.

In accordance with the specifications, and in addition to a test at runaway speed, a dead short-circuit was applied to the generator for 10 seconds with full-load excitation (corresponding to about 12 500 volts at no load) without damage to generator or switchgear.

Exciters.—One exciter is provided for each machine, and consists of a 200-h.p. overhung impulse turbine, supplied by the Pelton Co., of San Francisco, coupled to an induction motor, and a 125-kW 250-volt d.c. generator supplied by the Westinghouse Electric and Manufacturing Co.

There is also a spare exciter, of similar manufacture, consisting of a 400-h.p. overhung impulse turbine coupled to a synchronous motor, a 250-kW d.c. generator and a pedestal-type exciter. This machine serves to supply a.c. power for local service in the event of failure of back power when the main units are not running. All three exciters have provision for connection to a d.c. busbar and also to the control-battery charging panels in the control room.

Transformers.—The main transformers were built by the International General Electric Co. and are set on a platform above the tail-race between the power house and the switch house. Three single-phase oil-insulated water-cooled core-type transformers are provided for each unit. Each has a capacity of 11 000 kVA and a ratio of 11 000/50 800 volts, the low-voltage windings being connected in mesh and the high-voltage in star for a line voltage of 88 000 volts. These transformers are of the conservator type with calcium chloride breathers, and have an impedance of 8·71 per cent.

Four tappings are provided on the high-voltage windings, in steps of 2½ per cent above normal voltage. Alternating-current temperature coils are provided to indicate the temperature reached in the hottest part of the windings, and capillary-tube thermometers in the oil indicate its temperature on the outside of the tanks and are fitted with alarm contacts. Oil gauges are fixed on the conservators, and oil sampling cocks and filter connections are provided at the tops and bottoms of the tanks and on the conservators.

Considerable difficulty was experienced in drying the first bank by operation on short-circuit, some 60 days being expended for this purpose. The cores of the second bank were therefore removed from their tanks and placed in a shed through which hot air was passed.

THE SWITCH HOUSE.

The main generator leads consist of two 1·18-sq. in. (1 500 000 circular mils) cables, each of 1 360 amperes capacity, insulated for 13 000 volts and supported on 25 000-volt insulators. They are carried along the ceiling of the air duct and up to an auxiliary busbar in the roof of the switch house, whence connections are taken to potential transformers and switches.

The general lay-out, to conform with the wiring diagram (Fig. 2), includes two main 11 000-volt busbars of 4 in. × ¼ in. copper supported from the ceiling at a height of 48 ft. (14·7 m), only one being installed for the present two units. Above this is a cable room 6·5 ft. (2 m) in height devoted exclusively to the installation of control cables and conduits. Above this at a height of 55·7 ft. (17 m) are the main breakers and instrument transformers, while in the centre section at this elevation is the control room, completely shut off from the generator by a plate-glass bay window for its entire length. On the floor above the control room is the battery room, while in the wings, supported from the

FIG. 2.—Wiring diagram of electrical equipment in Serra power house.

roof beams, are auxiliary busbars for generators and transformers.

The battery has a capacity of 280 ampere-hours on the 8-hour rate at 250 volts, and is used for control circuits and emergency lighting. It is charged by the trickle-charge method.

The oil circuit-breakers and switchboards were supplied by the Westinghouse Electric and Manufacturing Co., and the 11 000-volt isolating switches and busbar supports by the Delta Star Electric Co., of Chicago. All the 11 000-volt equipment is insulated for 25 000 volts in order to give an increased factor of safety. All phases are separated by barriers consisting of concrete 3 in. thick in vertical runs and two thicknesses of $\frac{3}{4}$-in. transite asbestos in horizontal runs, the minimum clearance to earth being 10 in.

The 11 000-volt oil cell-type circuit-breakers, which are solenoid-operated, have a guaranteed rupturing capacity of 896 000 kVA at 11 000 volts. The isolating switches are lever-operated with a system of sequence locks for the protection of operators, and indicating lamps on the main control desk show the position of the switches at any time.

Many of the bolts for holding busbar supports and isolating switches were set in the forms before the concrete was poured, nuts being placed on either side of the wood to hold the bolts firmly in position; some of the bolts were split at the end and bent into "ram's horn" shape, and others had the ends bent over at right angles for a length of about 4 diameters. In order to determine whether the strength of the bolts as set in a 4-in. slab was equal to the strength of the busbar supports and would withstand an ultimate stress on short-circuit of 1 million kVA, it was decided to test four sets of bolts to destruction by a cantilever arrangement. The average failure was at 5 500 lb. on a $\frac{1}{2}$-in. bolt of the "ram's horn" shape in a 4-in. slab, and it was found that the failure occurred in the split of the bolt rather than in the concrete, but that, in any case, the pull was greatly in excess of that required for the calculated maximum short-circuit stress.

The local-service and station-service equipment is situated in the north bay of the switch house at the same elevation as the generator floor. It consists of two 600-kVA transformers stepping down from the east and west sections of the main busbar from 11 000 volts to 220 volts (star-connected). The low-voltage busbar feeds the exciter motors, the cranes, and the local and construction, light and power circuits, and a circuit stepping up to 3 800 volts for local services. It may be of interest to note that the synchronous motor of the 250-kW spare exciter is started by throwing in an oil circuit-breaker connecting its three phase leads to two phases and the neutral of the busbar, and then throwing over to the three normal phases by means of a second circuit breaker electrically interlocked with the first.

All the control cables are lead-covered and laid in galvanized corrugated cable-pans supported on pipe structures, cables carrying alternating current being kept separate from those carrying direct current. Although these cables are somewhat difficult to bring up to a control board of the bench or desk type, yet they should be vastly superior to rubber-covered wire in conduit owing to the extreme dampness to which they are subjected, and to the ease of inspection and maintenance which they render possible. The colour scheme in multiconductor cable also makes for rapidity in installation.

The switchboards are located in the control room overlooking the generator floor from an elevation of 23 ft. (7 m) above it. The glass window permits the operator at the main control board to see all units and the gate-opening indicators on the turbines, and cuts off the majority of the sound. Signals to the turbine floor are conveyed by mechanical signal devices of the ship's telegraph type with telephone attachment.

The main control board is of the desk or bench type with a mimic busbar indicating the position of all switches, while red and green lamps show whether the latter are closed or open at any time. One section of the board serves for one unit and one for the exciters and station-service equipment. Governor control and emergency shut-down switches are also installed on this board, while on the vertical section are the generator ammeters, wattmeters, power-factor meters and line ammeters. Voltmeters, frequency meters and synchroscopes are provided on a swinging panel. The relay board is situated behind the bench board and carries, in addition to relays, kWh meters and recording voltmeters and frequency meters. Behind the relay panel are the d.c. and a.c. feeder panels and the lighting panel, together with a panel for control of the local circuits, the breakers of which are connected to the station-service busbar 32·8 ft. (10 m) below.

On the east side of the control room is an annunciator panel and a transformer temperature-indicating panel with provision for future banks of transformers. The annunciator panel is of a special design with enamelled-wire coils for tropical power-house service, and has 48 drops connected to either a red, a green, or a white light at the top of the panel and a corresponding bell indicating the degree of urgency of the alarm. A special feature is that it is possible to disconnect the light and the bell at once, but the drop cannot be reset until the alarm contacts at the apparatus are open, indicating that the abnormal condition has been removed. A special 24-volt battery is provided for the operation of this equipment, and is charged by a Tungar rectifier.

A voltage-regulator panel of the Westinghouse vibrating type, with a section for each exciter, is located on the west side of the control room.

RELAY SYSTEM.

The relay system is designed to give a maximum degree of protection to the equipment. Differential protection for each generator is provided by Ferranti self-balancing current transformers and relays which operate multi-contact relays to trip off the generator field, the exciter motor and the generator-to-transformer and generator-to-busbar circuit breakers. The transformer differential protection consists of bushing-type current transformers on the high-voltage bushings of the transformers, and series-connected current transformers outside the delta on the low-voltage side: these actuate induction-type relays which in turn operate multi-contact relays to trip the breakers on the high- and low-voltage sides of the transformers.

Overload protection is also provided on the generators, the busbar-to-transformer connections and the high-voltage lines in a similar manner. Over-voltage protection on the generators is also provided, and the generator field circuit-breakers will not open until the generator oil-switches are open. The station-service transformers also have overload protection which trips their high- and low-voltage circuit breakers and both No. 1 and No. 2 exciter motors; and reverse-energy relays are provided to prevent feeding-back from the station-service busbar to the main busbar. Each of the multi-contact relays of each of the above systems gives an indication of operation on the annunciator panel.

The outgoing lines are provided with overload relays and selective differential current relays for balanced current between the two circuits (or more in the future).

INDICATORS AND ALARMS.

Owing to the small staff required for normal operation of the plant, numerous indicators and alarms are fitted, amongst which may be mentioned the following:—

(*a*) Temperature indicators and alarms on the generator main bearings and on the main transformers.

(*b*) Smoke indicators in the air ducts, giving an immediate indication of any smoke coming from the generator.

(*c*) A needle recorder on each turbine recording positively and mechanically the travel of the four needles of the two power and two relief nozzles, thus showing the full history of the machine and governor operation in dealing with the load variations. This apparatus records the penstock pressure in addition to the position of the main and relief needles.

(*d*) Rack-loss indicators on the trash racks at the surge tank.

A high- and low-water indicator in the tail-race is contemplated, but has not yet been fitted.

THE EARTHING SYSTEM.

Special attention was paid to the earthing system owing to the high resistance of the soil, which has caused trouble in other plants, owing partly to the lack of dissolved salts in the water and partly to the impermeable nature of the soil and underlying rock. It was thought that with a high-voltage neutral solidly earthed and connected solidly to the penstocks any unbalanced current would tend to follow the line of these to the reservoir which runs parallel to the trunk telephone lines from São Paulo to Santos, thus causing trouble on the commercial telephone circuits, the transmission-line earth wire being of $\frac{3}{8}$-in. Siemens-Martin steel and of comparatively high resistance. It was therefore decided to earth all the equipment inside the power house solidly to the penstocks and also to a copper plate in the tail-race, while a number of pipes were driven in the outdoor station to well below the water-level. To these pipes the high-voltage earths, including the transmission-line earth wire, were connected. These two systems were at first connected by bolted terminals. A series of tests was carried out during one night, and it appeared that half the current would be more or less evenly divided between the penstocks and the transmission-line earth wire and the remainder would pass through the pipe connection to earth; while with a total of 30 amperes in the earth the noise on the trunk telephone lines rendered conversation impossible. The normal earth current is, however, not measurable.

THE OUTDOOR STATION.

All the 88 000-volt equipment is located out-of-doors on the south side of the power house. The complete equipment will consist of a double busbar with a bypass from each transformer bank to the corresponding line: only a single busbar is installed for the first two units. The busbar and connections are of 4/0 B. and S. gauge (0·166 sq. in.) copper cable suspended from lattice galvanized-steel towers. The oil circuit-breakers were supplied by the Westinghouse Electric and Manufacturing Co.: they are solenoid-operated and frame-mounted and are rated at 600 amperes at 88 000 volts with a rupturing capacity of 915 000 kVA at that voltage. They have bushing-type current transformers for use with indicating ammeters and overload protection. The isolating switches were supplied by the Railway and Industrial Engineering Co., of Greensburg, Pennsylvania, and are lever-operated, 3-pole, double-break switches, horizontally mounted, those directly connected to the lines being so arranged that, by the removal of pins, two poles or one may be closed separately for testing purposes. A lightning arrestor of the International General Electric Co.'s oxide-film type is provided on each line. The lead-covered control cables for operation and control of the circuit breakers, and for connecting auxiliary switches on the isolators to indicating lamps on the main control board, are run in concrete trenches filled with sand and covered with removable concrete slabs.

THE TRANSMISSION LINE.

The transmission line consists of lattice galvanized-steel towers with suspension-type insulators and 4/0 B. and S. gauge (0·166 sq. in.) copper cable with $\frac{3}{8}$-in. Siemens-Martin steel earth-wire above. Each tower carries two circuits, 8-ft. vertical and 16-ft. horizontal clearances being provided. The conductors are vertically above one another, this type of construction being cheaper and not objectionable in the absence of sleet. The length of the line is 22 miles to the São Caetano terminal station on the east side of the city, or 41 miles to the Pirituba terminal station on the north-west side of the city.

The tower foundations are ground anchors consisting of a grid of steel channels and **I**-beams set in earth. The towers are built to a specification wherein the maximum loading likely to occur and the permissible stress in the material are given; and it is the practice of the company to test towers by direct loading, so as to ensure that adequate but not unduly heavy structures are provided.

The conductors are strung to a maximum tension of 3 300 lb., assuming 15 lb. per sq. ft. wind-pressure on the projected area of the conductor at 0° C. without ice. Joints are made with McIntyre copper sleeves when required.

The towers were built to a particularly exacting specification as regards galvanizing, as it has been proved in the Brazilian and other associated companies that a properly galvanized tower will show no signs of corrosion even after 30 years, and may therefore be assumed to be practically permanent. The average span in this lay-out was 787 ft. (240 m) and the maximum span 1 700 ft. (510 m). All the towers were located first on a profile made from a careful survey, on a scale of 1 : 5 000 horizontal and 1 : 1 000 vertical, using a celluloid templet showing maximum sag for a temperature of 55° C. (131° F.) and 15 lb. per sq. ft. wind-pressure. Although this work was done in the office no tower locations had to be changed in the field. A clearance of 26 ft. (8 m) above ground was maintained. The electrical design of the line shows a 6·5 per cent voltage-drop and a 3·2 per cent power loss with 33 000 kVA (the output of one generator) between the power house and São Caetano. In emergency nearly double this amount of power could be carried.

Fig. 3.—Wiring diagram of São Caetano terminal station.

Transpositions are arranged on the "intermittent system of barrelling," using three complete "barrels" between the power house and São Caetano; the communication circuits are co-ordinated with this arrangement and a total of six transposition towers are used.

Communication between the power house and the city is by means of two telephone circuits of No. 10 B. and S. gauge (0·008-sq. in.) copper wire run on hardwood poles along the transmission-line right-of-way and transposed in accordance with the Bell Telephone Co.'s standard practice for badly exposed lines. The instruments are protected by vacuum gaps, insulating transformers, fuses and drainage coils at both ends and at intermediate guard-houses.

It is probable that some of the future transmission lines will be carried up to the Serra on the west side of the penstocks and will follow the west side of the reservoir to the western industrial area of the city, thus avoiding the necessity of having more than 200 000 kVA on any one busbar.

The São Caetano Terminal Station.

A new terminal station for the Serra lines was built at São Caetano (see Fig. 3) on the east side of São Paulo in this centre of industrial development. Here there is a tap from each existing 88 000-volt circuit, both of which continue to the original Pirituba terminal station, with isolating switches on each side of the taps. The São Caetano station consists essentially of outdoor switchgear, step-down transformers, a pump house and a control building. The high-voltage switchgear is exactly similar to that in the outdoor station at the Serra power house, and the busbars are similarly constructed. The transformers, supplied by the Westinghouse Electric and Manufacturing Co., step down from 80 000 volts (mesh-connected) to 40 000 volts (star-connected) and have an impedance of 8·10 per cent. They are water-cooled, and for this reason an intake was constructed to take water from the Rio das Meninos, a small stream running through the station. This intake is divided into two sections and either can be shut off, by stop logs and a gate, from the river and from its 15-in. pipe line, which leads to a round well similarly divided and located just outside the pump house. At the far end of the pump house is a transformer repair house with an electric hoist, above which is a reinforced-concrete water tank with a sufficient supply and head of water to carry three transformer banks on full load for half an hour in the event of failure of all pumps. Valves are provided so that the pumps may work either on the tank or on the transformers direct, and a float-switch is mounted on the tank to control either pump, two 3-in. centrifugal pumps being the initial installation. The warm water from the transformers runs either to the river or to a hot-well, whence it may be pumped through nozzles in the spray basin and from here to the storage tank or transformers, thus forming a closed system, as the river water is often scanty in the dry season though adequate in the rainy months. There are also, in the pump house, two tanks for transformer oil and two for switch oil. These are of a capacity sufficient for the contents of one transformer or one switch, one tank of each pair being used for dirty and one for clean oil. These tanks are connected by piping to a clean and dirty bus-pipe and thence to a pump and filter press. Oil lines also run out in a pipe trench to the transformers, and oil in these and in the breakers can be filtered by means of a flexible hose connection.

The control building contains panels controlling incoming lines and outgoing feeders and local circuits, a battery and motor-generator set being provided for 125-volt control circuits and emergency lighting.

Capacity and Cost.

The present capacity of the Serra power station is 66 000 kVA, and the cost of the initial stage of development, including considerable provision for the future steps, is of the order of £2 000 000, and it is possible, by raising the reservoir-level to the maximum and by bringing in other water supplies, to provide sufficient storage and water for eight or more similar units, the cost of the power from the subsequent units being relatively low.

The São Paulo System.

The operation of the system is controlled from a load-despatching station in the city of São Paulo, and intercommunication between power stations and the city is by telephone, the lines being run along the transmission-line right-of-way.

The system load-factor is at present 56·5 per cent, and it is the general practice to run machines connected to the system at about 80 per cent gate opening, which gives in general their maximum efficiency, thus providing sufficient margin of capacity in the system so that if any machine is disconnected automatically the remainder can take up the load.

Voltage regulators with line-drop compensators are provided at all stations, and voltage is also regulated by hand at two synchronous-condenser stations each of 5 000 kVA capacity in the city.

Lightning storms are severe in this region and cause the majority of the faults on the overhead lines through flash-overs to earth on the insulators. To deal with these, rapid action of sensitive overload and directional and balanced-current relays is essential, and extensive tests are being conducted to determine the reactance and resistance of the ground, which are unusually high.

All substations are provided with batteries for use with the control circuits, and these serve also for emergency lighting in the event of a failure of supply.

Main-line electrification was begun some years ago and will presumably continue; also transmission lines will be extended further out than at present and provide for interconnections with smaller systems in the interior. At present the power supplied by this system is transmitted some 170 miles from the Sorocaba power house (or 190 miles from the Serra power house) to the most distant substation at Rincão on the Paulista Railway, the transmission voltage being 88 000 volts and the steadily growing peak load on the line being at present 17 000 kW. This railway operates at 3 000 volts (direct current), and the latest locomotives on order are rated at 2 400 h.p. (continuous rating).

The São Paulo Tramway, Light and Power Co., Ltd., is a subsidiary of the Brazilian Traction, Light and Power Co., Ltd., a Canadian company which owns the light, power, tramway, gas and telephone interests in Rio de Janeiro and São Paulo and the adjacent districts. The lay-out, design and construction of the Serra development scheme was carried out by the construction staff in São Paulo under Mr. A. W. K. Billings, a vice-president of the said company. The detail electrical design was done in the head office of the Canadian and General Finance Co., Toronto, Canada, as a subsidiary of the Brazilian Traction, Light and Power Co.

The author desires to express his thanks to the Brazilian Traction, Light and Power Co. for permission to present this paper, and to Mr. A. W K. Billings for assistance in its preparation.

A GEOMETRICAL ANALYSIS OF OPEN CARBON ARC PHENOMENA.*

By Professor W. Cramp, D.Sc., Member, and A. P. Jarvis, M.Sc., Student.

(*Paper first received* 13*th August*, 1929, *and in final form* 4*th February*, 1930.)

Summary.

The behaviour of a carbon arc with a resistance in parallel is first developed geometrically and proved experimentally. From this the conditions governing the musical arc are deduced and the growth of arc oscillations is traced. Geometrical methods are employed because no direct integration of the differential equations is possible.

The analysis shows that a musical arc, in which the current oscillates about a point on the volt-ampere characteristic, is possible but that it is unstable. An experimental example is given in Table 1. Stability is improved by the presence of the "hysteresis loop."

The tendency for the arc oscillations to grow until extinction ensues is next traced, and this leads to a discussion of discontinuous oscillations.

The necessity for the introduction of a thermal term in the equations, and its effect in permitting these discontinuous oscillations to persist, are explained, and an experimental example is given.

Observation of the discontinuous oscillations leads to the conclusion that no high-frequency inductance is essential, and experiments proving the correctness of this prediction are given, together with oscillograms of the current and voltage under these conditions. It is suggested that this phenomenon has important consequences for power station engineers, and that it forms the best starting-point for the examination of arc oscillations.

The dynamic characteristics for the examples quoted are deduced from the oscillograms, and their main features are analysed.

Introduction.

Much work has been done upon the singing arc since its discovery by Duddell in 1901. On the whole, though these researches have elucidated to some extent the causes underlying the Duddell oscillations, no complete theory covering all the observed facts has been satisfactorily established. The main reason for this is the lack of any mathematical method which is capable of deducing from the complicated conditions existing in the arc the resultant variations in pressure and in current.

In the present paper an attempt is made to show how this may be carried out geometrically, but it is necessary first to summarize briefly the present position of our knowledge regarding the arc characteristic, i.e. the relationship between current and voltage at the terminals of the electrodes. Mrs. Ayrton examined most thoroughly the so-called static characteristic, i.e. the relationship which exists between the above quantities when steady conditions have been established, and she deduced, for an arc of constant length, the relationship $V_a = A + B/i_a$, where A and B are constants, V_a is the arc voltage and i_a the arc current. Subsequently, Steinmetz showed that a similar expression, in which $\sqrt{i_a}$ was substituted for i_a, gave satisfactory agreement for the carbon arc and covered also instances of arcs between metals. The theory underlying the work of Steinmetz assumes that the vapour column of an arc tends always to work at a constant current density σ, so that its area a is directly proportional to the current carried; but this is to assume also that a thermal balance must have been reached, in the sense that the heat generated in the arc column must exactly balance that lost by radiation, convection and conduction. It is also evident that, since the vapour is always in contact with unvaporized electrodes, the average temperature of the arc column must remain almost constant. These assumptions do not hold if a sudden change takes place in i_a, for then heat must be supplied to produce a column of appropriate volume, so that a corresponding quantity of heat has to be supplied or is given up as the current increases or decreases.

Now at constant temperature the heat H in the vapour column is proportional to its volume, i.e. to $l \times a$. But $a = i_a/\sigma$, so that $H = k_1 l i_a/\sigma$. The power involved in a thermal change with constant length is $dH/dt = k_1 l/\sigma \times di_a/dt$. When the arc current is changing, therefore, there appears in the value of V_a an additional term, and the relationship between V_a and i_a for an arc of constant length whose current is rapidly changing becomes

$$V_a = V_a \text{ (taken from the static characteristic)} + k/i_a \times di_a/dt$$

where l is assumed constant and k is written for $k_1 l/\sigma$.

When these changes are taken into consideration, the relationship between i_a and V_a is no longer a curved line, but an area with a curved outline, and this is known as the dynamic characteristic. With a growing current the curve is to the right of the static curve, and for a falling current to the left. This leads to the so-called hysteresis loop of the arc, for which an equation of the form $a + b/i_a + k/i_a \times di_a/dt$ is appropriate. It will be seen that the new term is like a reactance wherein k/i_a simulates L.

A somewhat similar relationship occurs in the instance of a choking coil having an iron core, the coil being fed with a sinusoidal wave impressed upon a direct current of such a value that the iron is worked round the knee of its B–H curve. The effect of the new term is to delay the change of current through the arc, or rather to raise the arc p.d. for rising currents (di_a/dt positive) and to lower it for falling currents, so that there is now, between arc current and arc voltage, a phase displacement which increases with the size of the loop.

The existence of this loop complicates the calculations and its importance as affecting stability is referred to later in this paper. The form of the loop, however, depending, as it does, on the rate of change of current, is different for different conditions. Two main cases may be distinguished. The first is that in which a complete oscillation, entailing reversal, is forced upon the arc, as when the electrodes are fed by alternating current. In this instance the dynamic characteristic takes one of the forms shown by Simon,[*] and Norberg [†] has explained how the third term in the expression for arc voltage accounts to some extent for the peculiar shape. These alternating arcs, however, are not dealt with in this paper, so that their characteristics will not be considered.

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

The second variety is that which occurs when the arc undergoes a series of oscillations without reversal, and this covers most of the instances in connection with musical arcs. The characteristic is then of the form shown in Fig. 1, the width of the loop depending upon the amplitude of the current change and upon its rate, and the general shape upon the arc length. The particular illustration is drawn from an oscillogram taken by the authors when a carbon arc 1 mm long was fed simultaneously with alternating and direct currents so as to impress upon the arc a forced oscillation. To this end an a.c. supply of 30 periods per sec. was connected to the arc through a resistance and condenser in parallel with the d.c. supply, and the alternating and direct currents were so adjusted that the arc was not extinguished. The conditions were:—

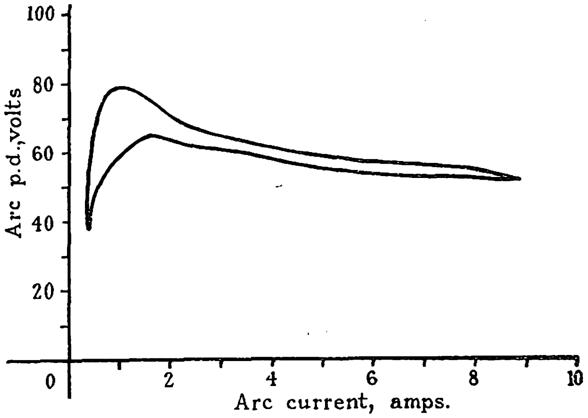

Fig. 1.

Carbons (solid) 18 mm and 11 mm respectively
Arc voltage (R.M.S.) 47·5 volts
Arc current (R.M.S.) 5·25 amps.
Alternating current (R.M.S.) 3·2 amps.
Direct current (R.M.S.) 4·3 amps.

If the ratio of alternating to direct current is reduced, the characteristic still forms a small loop, but in this instance narrower and more nearly elliptical, as is described later in this paper.

Another instance of the same effect, but this time with the direct current so adjusted that extinction occurs every period, is illustrated in Fig. 2, which was taken by the authors under the following conditions:—

Arc length 1 mm
Arc voltage (R.M.S.) 47·5 volts
Arc current (R.M.S.) 5·0 amps.
Alternating current (R.M.S.) 3·1 amps.
Direct current (R.M.S.) 4 amps.

The dotted line in this diagram indicates the static d.c. characteristic which had been previously determined for the same arc. It serves to illustrate the effect which is supposed to be covered by the third term in the arc equation.

The present paper does not deal with arcs other than those taking place between carbon electrodes in air, but it may be remarked that special dynamic characteristics, differing in shape from those illustrated, are found when the arc takes place between metal electrodes or when special means are provided for rapid extinction, as in the Poulsen arc; or, again, when the anode is water-cooled, or when the arc is deflected by an air blast. The peculiar conditions existing in these special examples have been investigated by the authors as well as by many other writers,[*] but they belong to a different category and will not be referred to further.

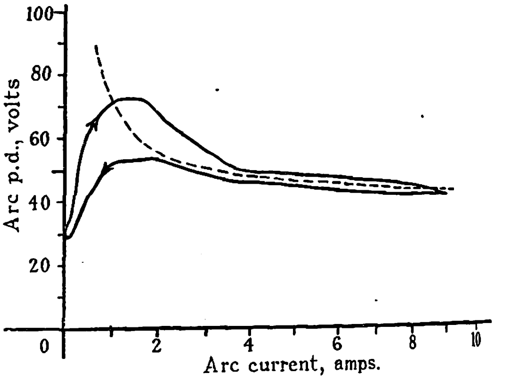

Fig. 2.

(1) An Arc with Parallel Resistance.

It is well known that a d.c. carbon arc cannot be maintained from a constant-potential supply without a series resistance; and the laws governing the magnitude of this resistance in terms of the arc volt-ampere characteristic have been clearly set out by Mrs. Ayrton.[†] It is not, however, so well known that when a resistance is in parallel with the arc the circuit can *only* be stable if the value of the shunt resistance exceeds a certain critical limit. The conditions governing this relationship have an important bearing upon the oscillations of the musical arc, and indeed form a convenient starting-point for the study of that phenomenon. The difficulty of dealing with the oscillations of an arc arises from the fact that a solution of the differential equations is not possible if the equation to the true arc characteristic be adopted. Beginning, however, with the consideration of a parallel resistance, a solution by geometrical methods can be developed whatever the shape of the arc volt-ampere curve may be. Moreover, the method is applicable to many other systems in which oscillations arise from an analogous cause, and is therefore of wide practical application. The oscillations of some musical arcs are maintained by the negative slope of the volt-ampere curve. If this curve be treated as a straight line (which is only justifiable over a very small range) the equations are easily solved. The main deductions, based on this assumption, are given for reference in the Appendix, where the arc characteristic is expressed in the form $V_a = K_0 - ri_a$, K_0 being the hypothetical value of the arc p.d. V_a when the current through the arc, i_a, is zero. Mrs. Ayrton's researches on the open carbon arc show that the static characteristic for a given length is more nearly expressed by the relationship $V_a = A + B/i_a$, while Steinmetz (with some theoretical justification) prefers the form $V_a = A + B/\sqrt{i_a}$, A and B being constants. But whichever of these alternatives be adopted, the same difficulty still arises with the equations and the geometrical analysis is useful as displaying the cause of this difficulty.

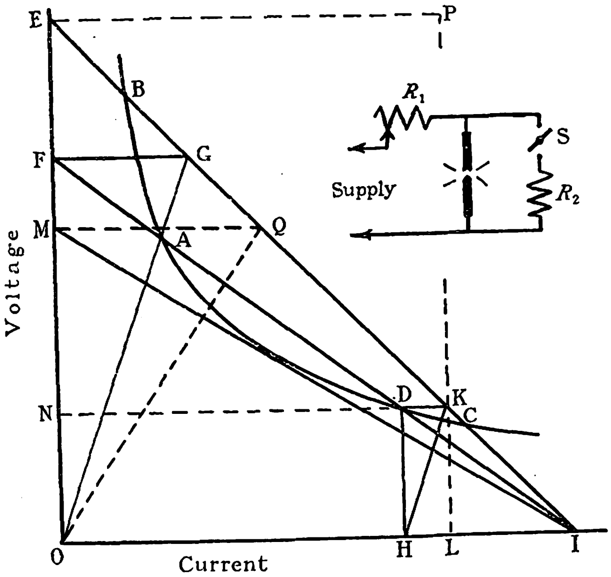

FIG. 3.—Arc with parallel resistance.

Suppose then that a carbon arc (Fig. 3) is fed from a constant-pressure source with a resistance R_1 in series and a switch S and resistance R_2 in shunt. Let OE and OI represent the axes of voltage and current respectively, and let the line ADC express the arc static characteristic. Then, following Mrs. Ayrton's construction, and with switch S open, if the line EI be drawn so that the tangent of the angle EIO represents R_1, the point C, where EI cuts the arc characteristic, is the stable point of working for the system. The other point of intersection, B, is unstable because dV_a/di_a is there negative and greater than E/I, so that Kauffman's conditions for stability are not fulfilled.[*]

Draw now a horizontal line FG in such a way that OF/FG represents the resistance R_2, and join FI. Then FI is the locus of the right-angled apex of all triangles within the triangle EIO that are similar and similarly placed to the triangle OFG. For example, in the triangles HDK, OFG:—

because FG is parallel to DK, FG: DK = FI: DI
and since FO is parallel to DH, FO: DH = FI: DI = FG: DK.
And the angle OFG = the angle HDK.
Therefore the triangles HDK and OFG are similar.

If the line FI also cut the arc curve, as at D, then the arc is stable at the point D with R_1 in series and R_2 in shunt. For since the triangle KDH is similar to the triangle GFO, DK is a current through R_2 corresponding to DH volts; and DH is also the voltage across the arc for the arc current DN, because D is common to the arc curves and to FI. Thus, if the arc is started with the current C, the switch S being open, the current will fall to NK when S is closed, and will divide so that ND passes through the arc and DK through R_2. If now the value of R_2 be reduced, the point F will approach O, and the angle FIO will decrease with corresponding changes in ND and DK. This process may be continued until F reaches the point M when MI just touches the curve ADC. If F is lowered still further, it is impossible for the necessary conditions to be fulfilled and the arc must be extinguished. Thus the lowest possible value of R_2 is OM/MQ. The following test proves this construction.

Using an experimentally determined characteristic for a 4-mm arc [approximately $V_a = 44 + (75/i_a)$] and a supply pressure of 220 volts, with a feed resistance $R_1 = 15{\cdot}1$ ohms, the current at point C was $i_a = 11{\cdot}2$ amperes, and the voltage $V_a = 52$ volts, whilst OI was 14·55 amperes, giving the line IM cutting the voltage axis at OM = 90 volts. Thus the resistance represented by OM/MQ is 90/8·6 = 10·45 ohms. By running this arc with a variable resistance R_2 in shunt, the arc continued to burn so long as R_2 exceeded about 10·5 ohms. By making R_2 large and gradually cutting it out, a condition was always arrived at when the arc was extinguished, and the average value of R_2 at which this occurred was 10·36 ohms. Having regard to the rapidity with which changes occur in the arc, this compares well with the theoretical figure of 10·45 given above.

It is evident that by an appropriate combination of R_1 and R_2 the arc characteristic could be experimentally determined with considerable accuracy.

It has been remarked that points such as A and B do not fulfil the conditions for stability. Consequently the composite circuit of Fig. 1 is only stable when:—

(1) FI cuts the arc characteristic, i.e. $\tan \angle FIO$ is greater than $\tan \angle MIO$.

(2) $\delta V_a/\delta i_a$ at the point of intersection with FI is less than $\tan \angle FIO$.

Now the slope of FI

$$= -FO/OI = -(OE - EF)/OI = -\frac{E - ER_1/(R_1 + R_2)}{E/R_1} = -\frac{R_1 R_2}{R_1 + R_2}$$

and for stability this must be greater than $\delta V_a/\delta i_a$.

---

[*] *Göttinger Nachrichten*, 1899, p. 243; also *Annalen der Physik*, 1900, vol. 2, p. 168.

If we adopt the straight-line relationship $V_a = K_0 - ri_a$ (see Appendix), then $dV_a/di_a = -r$; so that the limiting condition is $r = R_1R_2/(R_1 + R_2)$, which is the same as the condition for limiting steady operation of a musical arc, as given in the Appendix. If, on the other hand, we use Mrs. Ayrton's equation, $V_a = A + B/i_a$, then $dV_a/di_a = -B/i_a^2$, so that in the limit $B/i_a^2 = R_1R_2/(R_1 + R_2)$, or $i_a = \sqrt{[B(R_1 + R_2)/R_1R_2]}$.

Constant-Current Feed with Parallel Resistance.—In oscillating circuits the feed current is often maintained approximately constant by a large self-induction in the feed circuit. The construction just given may easily be extended to cover such conditions. If, for example, in Fig. 3, OL represents the selected constant current, then when $R_2 (= OF/FG)$ is in parallel with the arc, the arc current will be ND as before, and DK will be the current through R_2, NK being the line current because it lies on the perpendicular through L. Before the switch is closed the arc current is, in this instance, OL, and afterwards it is ND. The change in the arc current and voltage consequent upon the addition of a shunt resistance is therefore different, according to whether the feed current is or is not constant. If from the point L a tangent be drawn to the arc curve, the ratio of the ordinate at the point of contact to the horizontal intercept between the curve at that point and the line LP gives the minimum possible value of R_2 for the chosen current. It is a function of A, B and I, where I is the constant current, and its value is

$$R_2 = A^2/(AI + 2B) - 2\sqrt{[(B^2 + ABI)]}$$

As regards stability, the conditions appear to be similar to those in the circuit with constant feed volts. The authors hesitate to dogmatize, since they have made no experiments on this question.

(2) APPLICATION TO THE OSCILLATING ARC.

These expressions at once suggest the analogy between an oscillating arc and an arc with a shunt resistance. For in the former a capacity C, inductance L and resistance r_2 (Fig. 4) replace the shunt resistance in the latter, and only an alternating current can flow through the shunt circuit. Applying these considerations to Fig. 3 we obtain Fig. 4, and it follows that, if N_1C is the stable arc current before oscillation begins, then a half-wave of charging current through the condenser in the positive direction will be represented by a current rising from zero at C to a maximum at, say, DK and down again to C. The reverse half-wave is similarly represented by a discharge current from C to PQ and back to C. The feed current meanwhile goes from N_1C down to NK and back to N_1C; then from N_1C to N_2P and back. Similarly, the arc p.d. during charge goes from N_1 up to N and back; and during discharge from N_1 down to N_2 and back. Thus by means of this diagram the whole cycle can be studied. It is obvious that the change in arc p.d. synchronizes with that of the oscillating current; in other words, the a.c. circuit must operate at the resonant frequency. It is clear, also, that during the charge period the average p.d. is higher than during discharge. This accounts for the growth and maintenance of the oscillations.* For consider a maximum high-frequency current DK. At this instant the voltage across the resistance R_1 has fallen from EN_1 to EN, so that the difference NN_1 represents a rise of pressure from the mains on the oscillating circuit, which must be equal to or greater than the product of the current DK and resistance r_2. On discharge the current through R_1 has risen to N_2P and the corresponding pressure across the oscillating circuit has fallen to N_2, so that the condenser may be able to discharge itself against the resistance r_2. If the values NN_1 and N_1N_2 are greater than the product of r_2 into the corresponding values DK, PQ, the remainder is available for increasing the oscillating current exponentially until balance is established.

Hitherto the argument has proceeded on the assumption that the line DCQ is almost straight; but in fact the slope of CD is always a little greater than CQ, and moreover it increases rapidly beyond D towards B. Consequently if N_1N_2 is the resistance-drop in the a.c. circuit for the discharge current PQ, N_1N must be more than sufficient to produce the charging current DK, and the oscillations cannot be stable but must continually tend to an increase, due to the departure of the arc characteristic from the straight line. It is just here that the differential equations fail, and we arrive at the conclusion that the musical arc in which oscillations take place about C, without extinction of the arc, must be an exceedingly unstable phenomenon, if the arc characteristic is the assumed static curve.

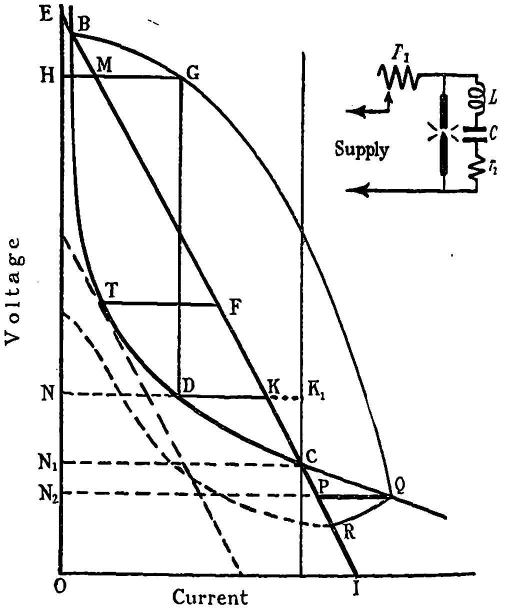

FIG. 4.

Before pursuing this further, we may note that if growth in succeeding cycles takes place, then the point D during each successive cycle travels further up the line QCD until it reaches the position where the horizontal difference between this line and EI is a maximum.

---

* These deductions are not in accord with the theory of Blondel (see *L'Eclairage Electrique*, 1905, vol. 44, p. 41). They are, however, supported by the equations in the Appendix.

This occurs at the point T where a line parallel to EI is a tangent to the curve TCQ. The conditions there are that $\delta V_a/\delta i_a = -R_1$. Adopting Mrs. Ayrton's equation, the maximum possible instantaneous value of the high-frequency current in the direction of charging the condenser is derived as follows:—

$$dV_a/di_a = -B/i_a^2 = -R_1$$

whence i_a under these conditions is $\sqrt{(B/R_1)}$. Now $E = (i_a + i_c)R_1 + V_a$, where i_c is the high-frequency or oscillating component of current; and so

$$E = (i_a + i_c)R_1 + A + B/i_a$$

On substituting for the value of i_a we get, for the maximum possible instantaneous value of i_c under these conditions,

$$i_{c_{max.}} = \left[E - A - 2\sqrt{(BR_1)}\right]/R_1$$

And, if we regard $i_{c_{max.}}$ as having a simple harmonic variation,

$$i_c = i_{c_{max.}}/\sqrt{2}$$

The point C in Fig. 4 is given by

$$i = \left[E - A + \sqrt{\left\{(A - E)^2 - 4R_1B\right\}}\right]/2R_1$$

Thus i_c/i, the ratio of high-frequency to direct current, is

$$2\left\{E - A - 2\sqrt{(BR_1)}\right\}/\left[E - A + \sqrt{\left\{(A - E)^2 - 4R_1B\right\}}\right]$$

If we take the values used in Fig. 6 for an arc 1 mm long, where $E = 248 \cdot 5$, $V_a = (41 + 30/i_a)$, $R_1 = 50$, then $i_{c_{max.}} = 2 \cdot 6$, $i_c = 1 \cdot 84$, $i = 4 \cdot 00$, $i_c/i = 0 \cdot 46$. Or, again, using the values of Table 1 and assuming the same equation for V_a, we find: $i_c = 0 \cdot 825$, $i = 2 \cdot 25$, $i_c/i = 0 \cdot 365$. In both instances the results are of the right order as compared with experiment, which is as much as can be expected when it is remembered that the wave-form and the arc equation are not likely to remain the same for many instants.

Stability of Excursions about C. Dynamic Characteristics.—It has been remarked that these oscillations must be unstable if they are dependent entirely upon the conditions hitherto assumed. But in fact they are more stable than this theory allows, and the cause of their stability is the so-called "hysteresis" of the arc. During discharge of the condenser the arc current is far larger than during its charge period; e.g. N_2Q in Fig. 4 is far greater than NK. Consequently the electrode temperature (upon which the shape of the arc characteristic depends) is different when the current is falling from N_2Q to NK as compared with the converse case. The result is that the line DQ becomes roughly elliptical, yielding the dynamic characteristic as illustrated in Fig. 5, which shows part of Fig. 4 enlarged. On the upward swing, then, when steady conditions have been reached, the current lines lie between TV and TK, instead of between CD and CK. After the maximum current has been reached at V, the horizontal intercepts travel round through D and lie between DS and KS. The reverse oscillation is represented by lines which lie between SI and SQ up to Q, and then by lines between TI and TQ. The chief effect of this modification is that the maximum high-frequency p.d. occurs at D, while the maximum current occurs at V, so that a phase displacement is introduced. The phenomenon may be easily understood by reference to the simple linear steady conditions given in the Appendix, where

$$i_c = K\sqrt{\frac{C}{L}} \sin \frac{t}{\sqrt{(LC)}}$$

and $$i_a = -\frac{R_1 + r_2}{R_1} i_c + K_1$$

Then $$I = \text{feed current} = K_1 - \frac{Kr_2}{R_1}\sqrt{\frac{C}{L}} \sin \frac{t}{\sqrt{(LC)}}$$

and $$V_a = E - R_1K_1 + Kr_2\sqrt{\frac{C}{L}} \sin \frac{t}{\sqrt{(LC)}}$$

The variable parts of arc voltage and current are thus in antiphase, as would be expected from the resonance conditions, and the mean high-frequency power is $(K^2r_2C)/(2L)$. If now V_a and i_a have an angular displacement other than O or π, the path described will be an ellipse with its major axis lying nearly along the original straight line; and for the same amplitudes the high-frequency power will be reduced in the proportion of $1 : \cos \phi$, where ϕ is the angular displacement from π. This ellipse is the simple counterpart of the loop in Fig. 5, caused by the quasi-reactance term $(K/i_a)(di_a/dt)$ mentioned in the introduction. Its effect is threefold, viz.:—

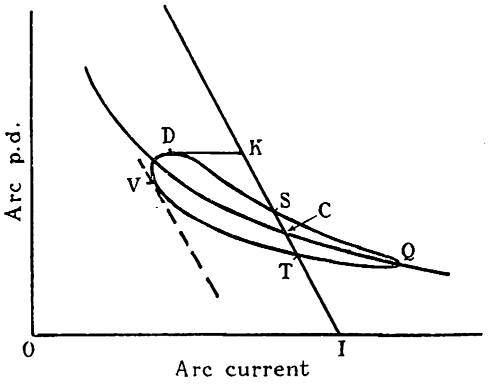

FIG. 5.

(1) It causes a change in the effective ratio of L/C because it is similar to a reactance.
(2) It alters the natural period of the whole circuit and disturbs the resonant condition so that the high-frequency current and arc voltage are no longer in phase.
(3) It tends to limit the high-frequency power and therefore the growth of the oscillation; in other words, it gives to this type of oscillation a stability which otherwise it would not possess.

The arc hysteresis loop, or dynamic characteristic, occurs to some extent in all instances, but it is only when the excursion is about some point where dV_a/di_a is small that it assumes the elliptical shape, and then the ellipse is of small importance. When the amplitude of the excursion is greater the dynamic characteristic is far less regular. The upper curve in Fig. 9 is deduced from the oscillogram shown in Fig. 7, and may be compared with Fig. 1, which it closely resembles; but it will be noted that from A to B the return curve lies above the outgoing line. This is not usual, but it often happens. It is due to the fact that in this region dV_a/di_a is small and i_a large. Consequently, in the p.d. equation

$$V_a = A + B/i_a + K/i_a \times di_a/dt,$$

the shape is controlled largely by the first two terms and any slight alteration of arc position or length (upon which A and B depend) is enough to interchange the two lines. On the other hand, the loop ACD is always present and lies in a region where dV_a/di_a is large and i_a small, and consequently it is much affected by the second and third terms. The physical explanation is simple if the peaks AD be joined as suggested by the dotted line in Fig. 7. Then the voltage curve follows the normal current line, i.e. represents the resistance-drop in a tuned circuit, while, in Fig. 9, C disappears and DAB becomes the ordinary characteristic. The hollow at C is entirely due to the response of the high-frequency inductance and feed inductances and resistances to the first change at A. In the present instance, the d.c. feed circuit had considerable inductance, which accounts for the rounded form at C. The authors have observed that when this is not the case the point C is lower and the curve far sharper. The twin peaks of Fig. 7 appear in almost all oscillograms. The opinions advanced hitherto upon the arc phenomena are not in accordance with the views of Blondel,* nor do they entirely agree with those of Pedersen,† but the present authors believe that they will bear close investigation.

Effect of Constant Current Feed.—Here, as in the preceding section, the behaviour of the arc when the feed current is kept constant may be inferred. Suppose, for instance, the vertical line through C (Fig. 4) represents the selected constant-current feed. Then when the arc current is ND, the current in the high-frequency circuit will be DK_1 instead of DK; and we conclude that for a given oscillating arc voltage greater high-frequency currents will flow with constant feed current. On the other hand, this greater current NK_1 will only correspond to the same voltage-rise N_1N as did DK; so that r_2 must be smaller. In other words, to cause the arc to oscillate with a high high-frequency resistance r_2, a high feed-voltage and external resistance are preferable to a constant-current feed. This is entirely borne out by experiment. It may be added that constant feed-current conditions are obtained in practice by making the resistance R_1 smaller but very inductive. Such an arrangement has the advantage that the damping introduced by high-frequency currents flowing in the feed circuit is reduced, and therefore a higher efficiency is attainable.

(3) DISCONTINUOUS OSCILLATION.

When, as in Fig. 4, the current has grown to the value TF, it must of necessity continue to flow, not by moving from TF towards C, but towards B; because beyond T the charging current actually falls with a rising voltage. Thus the harmonic oscillation about C is now superseded by a transient towards B. It will be seen later that B may never be reached, on account of differences between the static and dynamic conditions.

In order to show the theoretical manner in which this growth will take place, it is possible, for any given characteristic, to integrate the differential equations step by step, and this has been done, starting from the fundamental equations for an arc of 1 mm. They are as follow:—

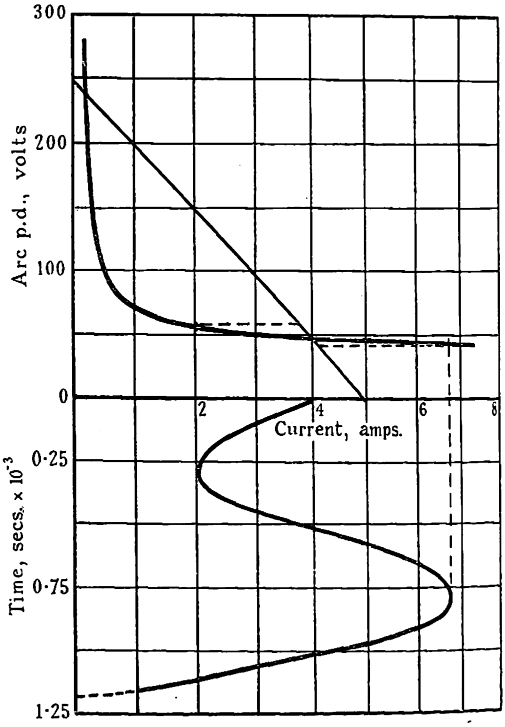

FIG. 6.—Predicted oscillation. Supply voltage 248·5; feed resistance 50 ohms.

(*a*) Feed circuit $V_a = E - IR_a$
(*b*) Arc circuit $V_a = 41 + 30/i_a$
(*c*) Oscillating circuit $V_a = r_2 I_c + \frac{Ldi_c}{dt} + \frac{1}{C}\int i_c\,dt,$

and $I = i_a + i_c$.

The conditions chosen for the calculation were:—

Applied volts = 248·5
Arc length = 1 mm
Feed resistance = 50 ohms
High-frequency inductance (L) = 5 066 μH
High-frequency resistance (r_2) = 1 ohm
High-frequency capacity (C) = 5 μF.

The natural period of the circuit is therefore about 1 000 periods per sec., and Fig. 6 shows in rectangular co-ordinates the growing wave and the original characteristic.

If the growth of the oscillation just described does not lead to complete arc extinction, it at least results in a current so small as to be incapable of maintaining anything more than a glow. Experiment shows, however, that, when once these conditions have been established and a point such as B in Fig. 4 has been reached, oscillation continues. We may assume, if we wish, that on approaching B the arc is extinguished and the pressure on the condenser circuit rises until it reaches the full line voltage OE, but it is not possible then for discharge to take place, for by hypothesis the arc current must be on the line TDC, and the line current on EI. Horizontal intercepts between these two are charging currents for the condenser. Discharge can only occur below C, as at PQ. In other words, the discharge region must lie to the right of EI, and so long as the arc characteristic is of the shape shown there is no such region between C and B. How then can the arc voltage travel from B to C again? The answer to this question is obtained from oscillograms, of which Fig. 8 is a typical example. From this it is seen that the condenser charging current is always near its maximum value when extinction occurs; i.e. to obtain this form of oscillation the circuit must be so arranged as to bring about extinction near the maximum intercept

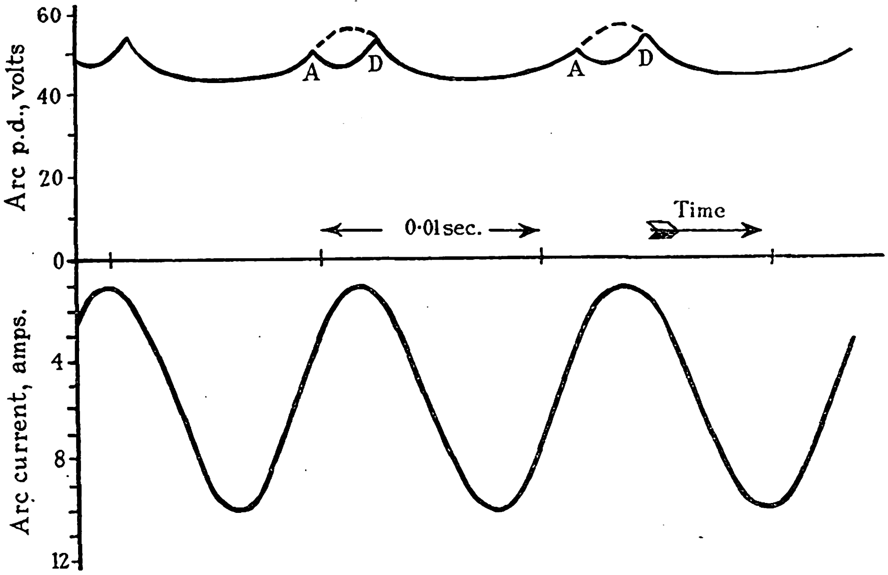

FIG. 7.—Non-extinguishing arc. Supply voltage 240; scales approximate.

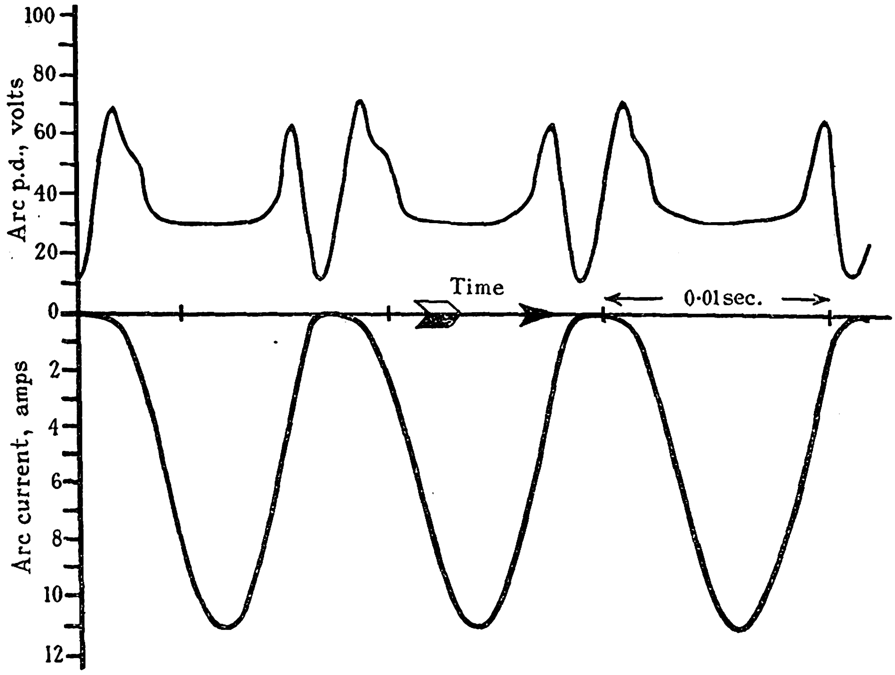

FIG. 8.—Extinguishing arc. Supply voltage 210; scales approximate.

TF (Fig. 4), so that on re-ignition the diminishing charging current may continue towards C. This condition means that when the arc current is small enough for extinction to occur the slope of the characteristic must not be greater than the slope of the resistance line. Now the shorter the arc the flatter the portion CDT. For example, to the family of curves derived by Mrs. Ayrton * the following equation applies:—

$$V_a = 38\cdot88 + 2\cdot074\, l + \frac{11\cdot66 + 10\cdot54\, l}{i_a}$$

where l is the arc length in mm. Thus, for constant l,

$$\frac{dV_a}{di_a} = -\frac{11\cdot66 + 10\cdot54\, l}{i_a^2}$$

If $l = 5$ and $i_a = 1$

$$\frac{dV_a}{di_a} = -64 \text{ (nearly).}$$

If $l = 1$ and $i_a = 1$

$$\frac{dV_a}{di_a} = -22 \text{ (about).}$$

If then the 5-mm arc be arranged on a 220-volt circuit with 40 ohms in series the stable current will be about 4 amperes. It cannot, however, oscillate with an amplitude exceeding 2·8 amperes, as at this current $dV_a/di_a = -40$. Its minimum current when oscillating will thus be 1·22 amperes, and it will almost certainly not be extinguished. It is an example of Fig. 7. If, however, with the same circuit conditions the arc length be reduced to 1 mm, the minimum arc current may fall to 0·74 before $dV_a/di_a = -40$, and the arc will most likely be extinguished. It approaches Fig. 8. Thus for a given circuit the discontinuous oscillation is more likely to occur with short arcs, its high-frequency current will be greater, and since the arc is extinguished the high-frequency amplitude must approach the value of the direct current, and the ratio of R.M.S. alternating- to direct-current feed must be about 0·7.

Table 1 gives details of two experiments which have almost the same circuit conditions and serve to confirm these contentions. The words "type A" and "type B" serve to distinguish the non-extinguishing and extinguishing arc respectively.

The last difference in this comparison is very clear to a musical ear, and can be traced immediately the change of type occurs. It is significant that the figures given by Duddell in his original paper on the musical arc † indicate that type B was his discovery, for the ratios of high-frequency to arc current in the two instances that he quotes are 0·86 and 0·9 respectively, under which conditions the arc must surely have been extinguished *every period*.

As further evidence of the two types of oscillation, reproductions of two sets of oscillograms are shown in Figs. 7 and 8, the former being type A. The conditions appropriate to these diagrams are given in Table 2.

Dynamic Characteristics of Extinguishing Arc.—The form of loop appropriate to an arc extinguished by a forced sinusoidal oscillation has been given in Fig. 2. When the oscillation is natural it is more complex. The lower curves of Fig. 9 are deduced from Fig. 8 and the physical explanations are exactly in line with those advanced for the upper curves. The intersection of the "go" and "return" curves is more pronounced than usual, but the authors have observed it on many occasions, and, having regard to the rapidity with which the arc changes its position on the electrodes, it is not surprising that these irregularities should occur. The ignition voltage need not be the d.c. supply voltage; it may be lower or higher, but, if higher, then the feed circuit as well as the high-frequency circuit must contain inductance.

C	154 μF	154 μF
r_2	0·6 ohm	0·6 ohm

Since the authors, in their interpretation of these arc figures, differ from other investigators, it is important that strong evidence to support them should be forthcoming. They have said:—

(1) That when the arc is extinguished by a natural swing, the slope of the characteristic must not exceed that of the resistance line.

* "The Electric Arc," Fig. 61.

† *Journal I.E.E.*, 1900–1, vol. 30, p. 251.

(2) That the dynamic loop may be caused by a heat change which simulates a reactance.

(3) That departures from such a loop, when not due to irregular working of the arc, are caused by the high-frequency and feed inductances.

The first point they think they have proved above. Fortunately, they have also found means of proving the other two by experiments upon an arc with no high-frequency inductance whatsoever.

The argument is as follows:—If an arc can be caused to oscillate with capacity but no inductance in shunt, the arc voltage can never rise above that of the supply, and there is no possibility of a swing about the point C, Fig. 4. Thus if, in Fig. 4, the inductance L be omitted and the arc oscillates, then the charging current will lie between BTDC and BMKC, but no discharge whatever can lie in this region. Therefore, charging will continue up to the point B, and if the arc extinguishes it will go on up to E, or to some lower point at which re-ignition occurs. Again, since the charging current will be large at first, but will tend to decrease, the di_a/dt term will at first be large and negative, and the dynamic characteristic should be well to the left of the static curve during charging, as, for example, the dotted curve in Fig. 4. On ignition the discharge will be extremely rapid and *must lie entirely to the right of* EI. This can happen if the di_a/dt term exists and is large enough to produce such an effect, as, for example, is suggested in Fig. 4 by the line BGQ. Then on discharge, for a feed current = HM, the current through the arc would be i_a = HG, and $k/i_a \times di_a/dt$ would be positive and represented by DG. Thus departures on both sides of the static curve will be expected, but the form of the loop cannot be predicted beyond saying that the arc current will increase to a maximum, say N_2Q when di_a/dt is zero, and because of this condition Q must be on or near the static curve and still to the right of EI. Then as the high-frequency current decreases di_a/dt will be negative until some point representing the minimum arc voltage is reached at R which corresponds to zero high-frequency current and must therefore be on EI. Beyond R the high-frequency current reverses, but di_a/dt is still negative because it is now the difference between the high-frequency current and the direct current which feeds the arc, and this term remains negative until the maximum reverse high-frequency current is reached. Thus the outward curve might be BGQR, and the return curve from R to B would be a line such as the dotted curve lying to the left of, or below, CDB. We must therefore consider the possibility of an oscillation with no high-frequency inductance.

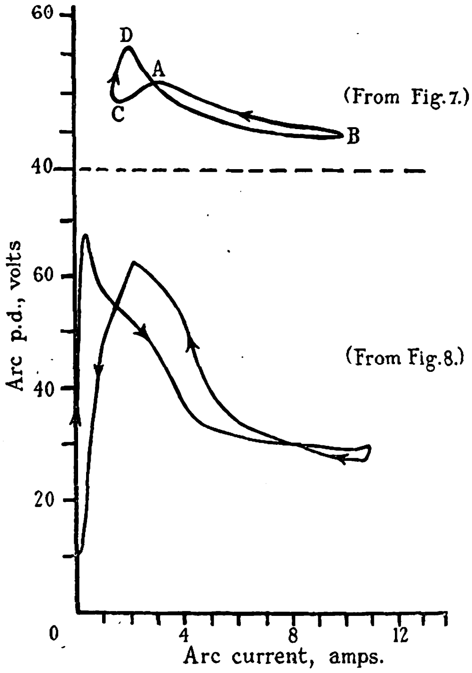

FIG. 9.—Dynamic characteristics.

(4) Oscillations with No Inductance.

It is obvious that if a condenser and a short-circuiting device in parallel be fed through a series resistance from a d.c. supply, the condenser can automatically charge and discharge, provided that the short-circuiting device operates at a high voltage and ceases to operate at a lower voltage. A well-known example is the behaviour of the neon lamp as determined by Pearson and Anson.[*]

Now although the characteristic of the arc is quite dissimilar from that of the neon lamp, the two have this much in common, that a higher voltage is necessary to start than to maintain the discharge. An arc, therefore, fed in the above manner, with no inductance whatever, should play the part of a short-circuiting device and show itself capable of giving out a musical note. This experiment was tried and the prediction was verified. It is interesting to note that Duddell's first oscillation was produced with no inductance other than that of a pair of long leads, but his effect disappeared when these leads were twisted together, so that he thought that the swing could only take place if inductance were present. The authors' experiments, however (made with very short leads to the condenser and a short arc), show that the high-frequency inductance is unnecessary and serves only to improve the wave-form and to fix the frequency. For when the inductance is omitted the frequency is determined for a given condenser, arc length and supply pressure, by the series feed resistance, just as it is with the neon lamp. The phenomenon is in fact a series of violent single-energy transients, of practical importance to the power engineer, since it illustrates the fact that destructive oscillations—probably the most destructive oscillations—may arise from a short-circuit in a cable system where no ordinary resonance exists at all. The example in Table 3 gives the conditions for an arc behaving in this manner.

Fig. 10 shows an enlargement of an oscillogram taken under the following conditions:—Line voltage 215, mean line current 5·2 amps., condenser current 25 amperes (R.M.S.), feed resistance 31·6 ohms, capacity 216·1 μF, arc length 1 mm. The action may easily be traced. At time T_1 the arc proper is extinguished momentarily, but the inter-electrode space (being ionized) continues to conduct, and the current through the arc rises from T_1 to T_2 while the condenser charges. The voltage curve

during this period has the usual shape for a condenser charged through a resistance from a source at nearly constant p.d. The small arc current, as measured from the diagram, averages about 1·76 amperes and therefore accounts for a fall of the applied p.d. from 215 to 150·2 volts. The condenser voltage at the beginning of charge is about 8·35, and at the end only 61·0, so that clearly the gap resistance breaks down at this low pressure. The calculated time required to charge the condenser from 8·35 to 61·0 volts with an applied p.d. of 150·2 through the resistance of 31·6 ohms is 32×10^{-4} sec. A similar calculation from the current wave gives about 51×10^{-4} sec. The corresponding time, as measured from the diagram, is about 40×10^{-4} sec. There are many possible causes for such discrepancies, e.g. the difficulty of making exact measurements from the oscillogram, the doubt as to the exact instants at which charge and discharge begin, variations in successive cycles, etc., so that it cannot be expected that the results should be of more than the right order.

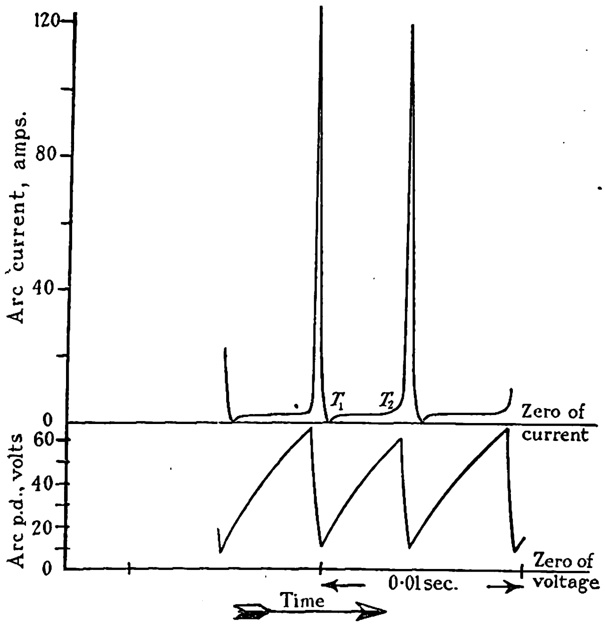

FIG. 10.—Arc with condenser in parallel.

As regards discharge, assume the time to be so short that the line-current variation is small. Then if V_a represents the arc voltage, i.e. the instantaneous condenser voltage, and V_1 and V_2 are its initial and final values,

$$V_a = A + B/i_a \quad \text{and} \quad i_a = -C(dV_a/dt)$$

So $$Bt = \tfrac{1}{2}C\left(V_1^2 - V_2^2\right) - AC(V_1 - V_2).$$

Taking, for instance, in this arc, $A = 33$, $B = 15$, we find $t = 0{\cdot}001$ sec., which might easily be true for the oscillogram. But such a calculation is really useless, depending, as it does, on an exact knowledge of A and B, and omitting the thermal term. If, for instance, $(V_1 + V_2) < 2A$, t is negative, which is absurd. We cannot therefore predict even roughly the time of discharge, or the maximum current. But the value of the latter, as measured, is no less than 126 amperes, and the R.M.S. value is 25, so that the ratio of maximum to R.M.S. value is about 5. Now, regarding the discharge wave as being roughly triangular, and remembering that the periodic time is about 45×10^{-4} sec., the time of discharge must be of the order of 5×10^{-4} sec. From the oscillogram it measures about $6{\cdot}0 \times 10^{-4}$ sec., so that the ratio of time of charge to time of discharge is 40/6·0 or 6·3, and the agreement with the rough theory is as good as can be expected. The main point to be noticed is that the average charging current is small and the time long as compared with that of discharge; also that, although extinction occurs every period, it is immediately followed by a time during which a small but increasing current flows, such as might occur if a glow remained between the electrodes. In many experiments the authors have found similar evidence, accounting for the low re-ignition voltage.

Oscillograms such as Fig. 10, involving the use of a condenser only, form an excellent method of studying arc transients, because the arc and condenser voltages are always the same. By the gradual introduction of inductance into the high-frequency circuit the change of the wave form may be traced, as well as the alteration from a frequency controlled by the feed resistance to one that is determined by the natural high-frequency period, and such records have been obtained. They involve, however, too long a discussion for this paper and must be postponed for some future occasion. It should be noted that for these experiments the arc length must be kept very short (which is probably why the phenomena were overlooked), and that the frequency is dependent upon and very sensitive to the length, because both of the constants A and B involve the length l of the arc. Thus if we write, with Mrs. Ayrton, $A = A_1 + A_2l$ and $B = B_1 + B_2l$ and substitute in the equation for discharge we get:—

$$t = \frac{C(V_1^2 - V_2^2)}{2(B_1 + B_2l)} - \frac{(A_1 + A_2l)C}{B_1 + B_2l}(V_1 - V_2)$$

showing that, in general, greater arc length results in shorter times of discharge.

Finally, Fig. 10 shows how high the ratio of R.M.S. high-frequency current to the d.c. feed current may be for these single-energy transients. In that example it is 25/5·2, or 4·8, as against 0·524 and 0·718 in Table 1. This is, however, by no means the limit. Instances could be cited in which the ratio was far higher, approaching 20; but of course a comparatively small resistance in the high-frequency circuit quickly reduces this large figure.

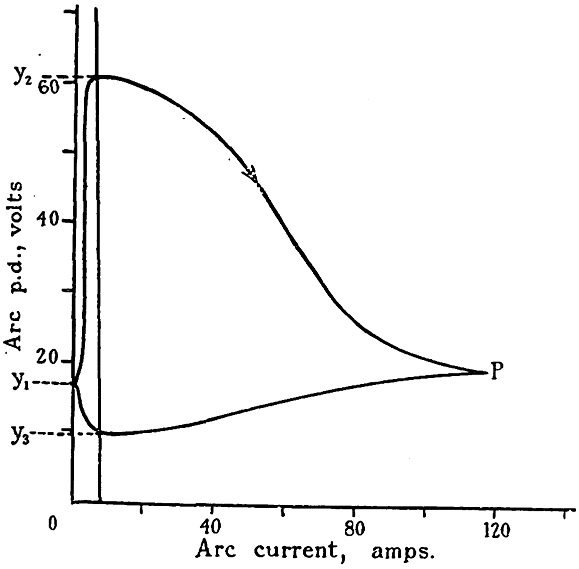

FIG. 11.—Dynamic characteristic of arc with condenser in parallel.

Fig. 11 shows the dynamic characteristic deduced from Fig. 10 by direct measurement of corresponding ordinates. Referring to this diagram, at y_1 the arc is extinguished. At y_2 re-ignition begins and y_3 marks the minimum condenser pressure. Thus charging takes place from y_3 through y_1 to y_2. The remainder of the curve is discharge. The line Py_3 in the dynamic characteristic is extremely difficult to deduce with precision from the arc-current/arc-voltage waves. The authors believe that as drawn it is as nearly as possible correct, having regard to the fact that the resistance line must, in their view, pass through y_2 and y_3, as shown.

The area of the loop has no great significance; it must not be confused with an indicator diagram or a hysteresis loop, for it does not represent work. The loop does, however, illustrate the mechanism of oscillation and it has a particular value in that it enables a link to be established between Duddell oscillograms and dynamic characteristics obtained by a cathode ray; but that also must be dealt with on a future occasion.* It shows, too, the immense effect on the arc characteristic of the rate of change of current, and confirms the likelihood of the general arc equations. From such a figure the current and voltage waves upon a time base may be derived. For if i_c represents the condenser current, then $i_c = CdV_a/dt$; and $dt = CdV_a/i_c$. Now each abscissa in Fig. 11 between the resistance line and the curve is a value of i_c, so that if the curve be intersected by a number of equally spaced horizontal lines representing δV_a the corresponding increment of time may be obtained by multiplying δV_a by the capacity C and dividing it by the appropriate value of i_c. Adding successively the time increments, we may plot them against i_c and thus invert the process by which Fig. 11 was obtained. Since for very high frequencies the cathode-ray oscillograph must be used, and since with that instrument it is possible to take the dynamic characteristic, the value of the above process is evident. When there is inductance in the high-frequency circuit, other methods must be substituted, which again emphasizes the value of the single-energy transient as a starting point for the examination of the arc.

CONCLUSIONS.

There are three ways in which a d.c. solid carbon arc may oscillate. Of these, the first or " A " type consists of excursions about a point upon a straight-line characteristic. The second (or " B " type) and commonest is a set of double-energy transients involving arc extinction every period or every few periods. The authors have found experimentally that a train, consisting of a growth from the straight-line condition, ending every two or more periods with arc extinction, does frequently occur. The third type is obtained with no inductance in the high-frequency circuit, and consists of a train of rapid single-energy transients around a wide loop.

The geometrical solution of the problem shows that, on the basis of the static characteristic, the maximum value attainable by an oscillation of the first and second kind is indicated by the value TF in Fig. 4. It is certain, however, that a loop due to the thermal term exists in these discharges also, with the result that oscillation about C takes place not along, but around, the line DCQ (see Fig. 5). This departure from the static curve is not very pronounced when the oscillations are small and the frequency low; but, as the oscillating currents increase or the frequency rises, di_a/dt becomes larger and the loops more important. In every instance the moment of extinction (or of minimum arc current) is almost certainly dependent upon the modification of the characteristic introduced by the thermal term. The fact that with small currents and low frequencies the behaviour of the arc can be fairly estimated from the equations of the Appendix shows that the departures from the static characteristic cannot, under those conditions, be serious. In short, no loop is theoretically necessary for oscillations of the A or B types, though it may exist; but without such a loop the third type would appear to be impossible.

---

* See *Electrical Times*, 1930, vol. 77, p. 1066: " The Indicator Diagram of an A.C. Circuit."

The authors wish to acknowledge the assistance rendered by Mr. E. G. Ashton, B.Sc., in connection with some of the oscillograms analysed in the course of their work.

APPENDIX.

Referring to Fig. 4, let E be the constant applied pressure, V_a the voltage across the arc, i_a the arc current, i_c the current in the high-frequency or condenser circuit, and I the sum of i_a and i_c. Then we have the following equations:—

$$V_a = E - IR_1 = E - R_1(i_a + i_c) = L\frac{di_c}{dt} + r_2 i_c + \frac{1}{C}\int i_c\,dt$$

Now let the arc have a straight-line negative characteristic so that $V_a = K_0 - ri_a$. Then K_0 is the hypothetical value of V_a when the arc is extinguished, and $di_a/dV_a = -1/r$.

Thus
$$\frac{dV_a}{dt} = \frac{R_1 r}{R_1 - r}\cdot\frac{di_c}{dt}$$

and
$$i_a = -\frac{R_1 i_c}{R_1 - r} + K_1$$

K_1 being the steady value of the arc current when $i_c = 0$. This equation shows also that i_a increases as i_c decreases. We thus obtain as the general equation for the oscillating circuit:—

$$\frac{d^2 i_c}{dt^2} + P\frac{di_c}{dt} + Qi_c = 0,$$

where $P = \frac{1}{L}\left(r_2 - \frac{R_1 r}{R_1 - r}\right)$ and $Q = \frac{1}{CL}$.

Assuming $P^2/4$ to be less than $1/(LC)$, oscillations are possible in the condenser circuit. Further, if K is the value of V_a when $t = 0$, and $q = \sqrt{\left[\frac{1}{CL} - \frac{1}{4}P^2\right]}$

then
$$i_c = \frac{K}{qL}\sin qt\epsilon^{-\frac{1}{2}Pt}$$

which will increase indefinitely if P be negative, i.e. if $R_1 r/(R_1 - r)$ is greater than r_2. For operation at a steady value of i_c, $r_2 = R_1 r/(R_1 - r)$ or $r = R_1 r_2/(R_1 + r_2)$, a difficult condition to maintain. Then

$$i_c = \frac{K}{qL}\sin qt$$

and
$$i_a = -\frac{r_2}{r}i_c + K_1 = -\frac{R_1 + r_2}{R_1}i_c + K_1$$

also
$$I = -\frac{r_2}{R_1}i_c + K_1$$

Thus K and K_1 are the co-ordinates of the characteristic at which the arc works with the given values of E and R_1, and with the high-frequency circuit open; also the feed current I cannot be steady but varies with a slope that is the inverse of the slope of i_c.

THE THERMAL RESISTIVITY OF SOLID DIELECTRICS.*

[REPORT (REF. L/T41) OF THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION]

(*Paper first received 3rd July,* 1929, *and in final form 17th January,* 1930.)

PREFACE.

As part of its comprehensive programme of Researches on Dielectrics, the Association has carried out an experimental investigation on the thermal resistivity of dielectrics.

Before undertaking this research a questionnaire was sent to all interested members, and the replies received showed that there was a serious lack of data on this subject and that the results obtained by other investigators did not apply sufficiently accurately to the materials at present in use in this country, neither did they take into account some of the many variables which are introduced during the manufacture of electrical machinery and apparatus.

The experimental investigations made for the E.R.A. were undertaken by the National Physical Laboratory, and for obtaining the required data new methods of test were developed and are described in this report.

During the progress of the investigation the Research Laboratories of the Metropolitan-Vickers Electrical Co., Ltd., carried out a separate investigation on the thermal resistance of air films. The results of this research were kindly placed at the disposal of the Association and have been included as part of this report.

Although there are many other features connected with the thermal resistivity of dielectrics which have not yet been investigated, it is felt that a description of the new methods of test specially developed for this work by the National Physical Laboratory and the valuable data already obtained will be of considerable practical use.

In the present report a detailed record has been given of the results obtained. This, it is considered, is required by those wishing to make a close study of the subject.

The Director of the E.R.A. will be pleased to receive comments from those who may have occasion to use the data recorded in this report.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

INTRODUCTION.

In electrical machinery and apparatus a large proportion of the heat resulting from energy losses in the copper and iron has to pass through the electrical insulating materials. As the latter are also heat insulators, a considerable difference in temperature on the two sides of the insulation may be required to cause the passage of the heat from the copper or iron to the cooling medium. As both the rating and reliability of the machine is largely determined by the maximum temperature of its insulation, a study of the thermal resistivity of electrical insulating materials is of considerable importance.

Tables recording values for the thermal resistivity of dielectrics are of little use without some knowledge of the degree of success with which they may be applied to practical cases. For this reason a study has been made of the features which usually affect the flow of heat through electrical insulation as applied in practice.

After reviewing the work of other investigators, new methods of test were developed. These have enabled the required features to be studied with an accuracy believed to be greater than has been obtained during any previous research on the subject.

After investigating the effect of such features as the degree of contact, mechanical pressure, temperature range, repeated heating, uniformity of resistivity over large areas, numbers of layers, etc., the true thermal resistivity of a large number of typical samples of various classes of solid dielectrics was determined.

Tests were then made on bars insulated in members' works by the same processes and with the same materials as are used for turbo-stator bars. The effect of different manufacturing processes on the thermal resistivity was determined.

Another section of the research was devoted to a study of different types of insulation used between sheet-steel stampings. These tests were also made on commercial samples supplied by members.

Part IV of the report records the results of an experimental investigation carried out by the Research Laboratories of the Metropolitan-Vickers Electrical Co., Ltd.

In researches on the transfer of heat through bodies, it has usually been the practice to express the results in terms of thermal conductivity.

A material has unit thermal conductivity when it conducts one gramme calorie of heat per second across opposite sides of a centimetre cube, the difference in temperature between the sides being 1° C.

In considering heat transference in electrical machinery and apparatus it is more convenient to express the above-mentioned property in terms of thermal resistivity.

In its report on the heating of buried electric cables, Ref. F/T12, the E.R.A. used the symbol K to express thermal resistivity, and defined it as the temperature-difference in degrees Centigrade to cause a transfer of energy at the rate of one watt * between opposite faces of a centimetre cube.

As in previous publications by the E.R.A., the thermal resistivity K of the materials is in this report always expressed in terms of watts, degrees Centigrade and centimetres.

When it is required to express the thermal resistivity in terms of an inch cube, the values given for K must be divided by $2 \cdot 54$.

When it is required to compare the values given for K, the thermal resistivity, with thermal conductivity values k expressed in gramme calories per second per centimetre cube, the following conversion formula may be used:—

$$\text{Thermal conductivity } k = \frac{0 \cdot 24}{\text{Thermal resistivity } K}$$

Part I.

A STUDY OF THE THERMAL RESISTIVITY OF SOLID DIELECTRICS WHEN TESTED IN SHEET FORM, AND OF THE FACTORS WHICH INFLUENCE THE FLOW OF HEAT THROUGH THEM.

(a) *Materials.*

The materials examined in this section of the research included typical samples of the following classes of solid dielectrics obtained from members:—

Papers and pressboards.
Varnished cloths and silks.
Vulcanized fibres of thicknesses ranging from $\frac{1}{8}$ in. to $1\frac{1}{8}$ in.
Varnished paper boards.
Ebonite.
Mica, micanite and micafolium.

(b) *Methods of test.*

For obtaining information on the true and on the apparent resistivity of the above range of types and thicknesses of dielectrics it was found necessary to develop more than one method of test. Whenever feasible, both the heat input and the heat output are measured independently. This is an important feature of the methods employed, for it enables a check to be kept on the accuracy of the thermal measurements.

The tests developed and the purposes for which they were mainly employed are given below:—

(i) *Apparatus No.* 1.

The first apparatus is shown diagrammatically in Fig. 1. It was constructed for the study of the thinner materials ranging in thickness from $0 \cdot 002$ cm up to $0 \cdot 05$ cm.

A $1\frac{3}{4}$-in. diameter copper rod 8 in. long was hollowed out to a depth of 4 in. and a heating coil inserted, as shown in the diagram. The specimen under test rested on the top surface of this rod, and superimposed was a water-cooled copper rod 4 in. in length pressed down by a spring. The top rod was surrounded on its outer surface by a copper spiral, through which a steady stream of water flowed. The temperature-rise of the water was measured by a set of differential thermo-junctions of copper-constantan. One degree rise in temperature of the water corresponded to 250 micro-volts in the differential flow couples. When the specimen

---

* One watt = 1 joule (or $0 \cdot 24$ gramme-calorie) per sec.

NOTE: Some idea of the order of magnitude of the values given in the various tables can be obtained from the following values taken from *Smithsonian Physical Tables* (7th ed.). When temperature is in the vicinity of 100° C., k for pure copper is $0 \cdot 908$. Therefore $K = 0 \cdot 264$. At a similar temperature k for wrought iron is $0 \cdot 143$. Therefore $K = 1 \cdot 68$.

had been inserted between the blocks pressure was applied by means of the spring plunger and the magnitude of this pressure determined by the scale reading. Most of the tests with this apparatus were carried out under a pressure of 24·8 lb. to the square inch.

To reduce heat loss both the hot and the cold bars were enclosed in metal cases packed with insulating material. The surfaces of the copper bars were ground plane to an accuracy of 1/10 000th of an inch. By making the surface to this degree of accuracy, contact resistance between the copper rods and the material under test would be due to the irregularities of the specimen and not the irregularities of the bar surfaces.

FIG. 3.—Apparatus No. 3 for testing thin specimens by comparison of temperature gradients.

(ii) *Apparatus No.* 2.

For the thicker material another apparatus was constructed, which is shown in Fig. 2. In this the heating coil is in the form of a flat disc, and two samples of the material are employed in the test. The advantage of this arrangement is that a considerable reduction in the magnitude of the correction for the heat loss from the heating coil is effected.

Thermo-couples were attached to the shallow copper case around the heating coil and also to the two " cold " bars. Each " cold " bar was water-cooled, and the temperature-rise of the water observed by differential thermo-couples disposed as shown in Fig. 2. The arrangement for applying pressure was a " dead-weight " plunger carrying lead weights amounting to 57 lb., which was equivalent to a pressure of 23·5 lb. per sq. in. In both No. 1 and No. 2 apparatus the plunger was thermally insulated by the interposition of a distance piece of ebonite. The metallic surfaces which came into contact with the specimen were ground true, the accuracy being within 1/10 000th of an inch to a true plane. In assembling the apparatus for an experiment a simple form of gauge was required to ensure that the axes of the two copper blocks and the heating coil were in line.

The tests were made at a series of steady temperatures up to the maximum specified for the class of material under investigation, and one or more repeat readings taken when cooling down. In the majority of cases the repeat readings differed by a few per cent from the values obtained initially.

This may be due to some permanent physical change in the properties of the material due to heating or hygroscopic changes. It is also possible that some of the materials soften slightly on heating, and the applied pressure would then bring the copper surfaces into more intimate contact with the material.

A number of experiments were made to ascertain whether there was any systematic difference in the results obtained from the two forms of apparatus; the differences were negligible. For example, a test on paper board, L. 135 (thickness, 0·51 mm), gave on No. 1 apparatus a resistivity value *K* of 615, and on No. 2 apparatus 590, at a mean temperature of 30° C. A specimen of treated silk, No. L. 120 (thickness, 0·12 mm), gave on No. 1 apparatus the value 715, and on No. 2 apparatus 712, at a mean temperature of 30° C.

(iii) *Apparatus No.* 3.

As shown in Fig. 3, this differed somewhat from the two described above. It consisted of two copper bars each 14 in. in length. One was provided with a heating coil and the other with a cooling coil. These were attached to the extreme ends of the bars. Thermocouples were arranged at regular intervals along both bars so that the temperature gradient could be observed. The bars were supported vertically, the lower one being fixed while the top one was movable. Definite pressures could be applied to the top bar by means of a lever and weights.

In this apparatus the quantity of heat flowing into the specimen and out of it was obtained by observations of the temperature gradient along the copper bars and a knowledge of the thermal conductivity of the copper. The two surfaces were amalgamated so that good thermal contact with the specimen was ensured. In order to determine the thermal resistivity of the two mercury films, which were always present when a specimen was interposed between the bars, some tests were made using a sheet of iron instead of the specimen. This sheet of iron was of uniform thickness, amounting to only 0·002 in. From observations of the discontinuity in the temperature gradient across the mercury joints and the thermal conductivity of the iron specimen it was calculated that the thermal resistivity *K* of the mercury film amounted to 0·067 for an energy transference at the rate of 1 watt per cm^2 of area.

With this apparatus two thicknesses of a sample of mica were tested, one being 0·005 in. and the other 0·01 in. The results obtained were in good agreement, as shown below:—

Thickness of specimen	Thermal resistivity K
0·005 in.	177
0·010 in.	174

These results were obtained with the ends of the bars in contact with the specimen well amalgamated. This apparatus is not well adapted for the study of anything but thin materials. If the thermal resistivity of the material is high, then the temperature-drop across the specimen is large and the gradient along the two bars small. As it is necessary to measure the gradient along the bar in order to obtain the conductivity, the use of this simple form of apparatus is limited.

(iv) *Apparatus No.* 4.

The irregular nature of the surfaces of most of the materials as supplied commercially was a serious obstacle to the use of plain contact plates, and necessitated recourse to amalgamated plates, so a form of apparatus was then devised with the object of facilitating assembly when the surfaces were flooded with mercury.

Layers of asbestos paper

FIG. 4.—Apparatus No. 4 for general-purpose testing. Suitable for specimens of large area.

The same instrument also served for the study of the variation in conductivity over the area of a large sheet, and proved to be of general utility.

Owing to the difficulty of assembly when two test specimens are employed, it was decided that the design should be such as to require but one sample, and, further, that the hot and cold surfaces should align automatically without any further manipulation once they had been brought into contact with the faces of the specimen.

A study of Fig. 4 shows how these aims have been achieved. The heating coil is clamped between two flat copper discs partially embedded in a block of ebonite; the amalgamated face is horizontal and face downwards. The complete heating unit is carried on a spindle working in guides, and once it is properly aligned with the cold plate these guides ensure that the hot face registers correctly with the cold face. This automatic alignment of the two surfaces is essential when point-to-point tests have to be made on large-sized sheets, as shown in Fig. 4, although it is more usual for the test specimen to be in the form of a circular disc of the same diameter as the hot and cold plates.

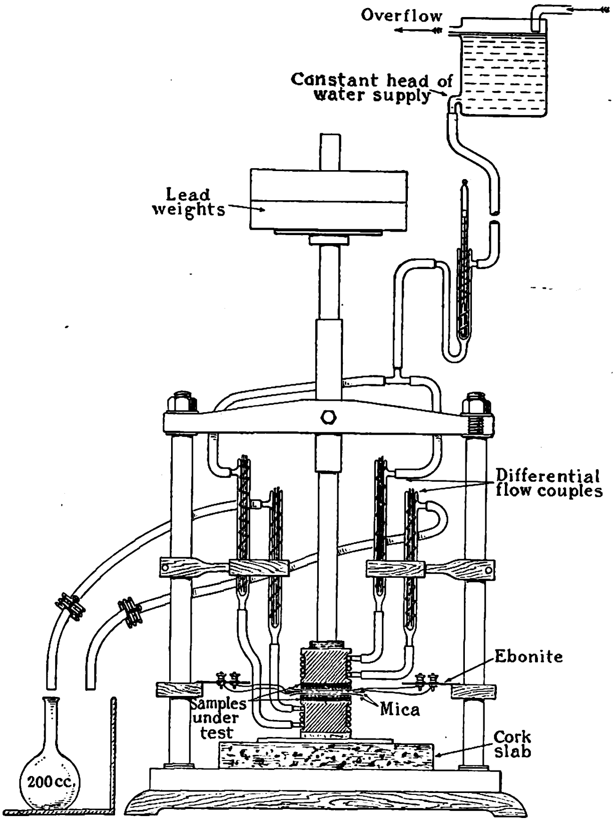

Fig. 5.—Apparatus No. 5 for testing without mercury films.

The cold surface is the end of a cylindrical block of copper maintained at a constant temperature by the steady circulation of water.

The temperature of the inlet water to the "cold" block is so adjusted that the mean of the inlet and outlet temperature is equal to the temperature of the surrounding atmosphere; this eliminates the correction for heat loss or gain from the block.

The temperature-rise of the water is measured by a pair of differential flow couples.

The watts dissipated in the heating coil are determined by observations of volts and amperes. After correction for the small heat leakage through the back of the hot plate, the energy dissipated in the heating coil is very nearly equal to the heat absorbed by the water flow. The data obtained in a typical experiment, such as those for light grey fibre (see table 11), will show the order of agreement obtained.

Experiment on Light Grey Fibre L. 113.

Pressure	21 lb. per square inch
Temperature of hot face ..	39·7° C.
Temperature of cold face ..	19·9° C.
Correction for gradient through mercury film	0·1 deg. C.
Hence true temperature difference ($t_1 - t_2$)	19·7 deg. C.
Amperes in hot plate resistance coil	0·5791
Volts at terminals	12·78
Watts	7·40
Correction for heat transmitted through back of hot plate	1·20 watts
Hence watts supplied to hot face of specimen (W) ..	6·20
Rate of water flow	200·0 cm³ in 126 secs.
Temperature-rise of water ..	0·93 deg. C.
Hence watts absorbed by water flow	6·15
Area of specimen (A)	15·59 cm²
Thickness of specimen (d) ..	0·141 cm

$$\text{Thermal resistivity } (K) = \frac{A \times (t_1 - t_2)}{W \times d}$$

$$= \frac{15 \cdot 59 \times 19 \cdot 7}{6 \cdot 20 \times 0 \cdot 141} = 351$$

(v) *Apparatus No.* 5.

Apparatus No. 5 is illustrated in Fig. 5. It resembles apparatus No. 2, but has a different arrangement of thermo-elements and an improved heating coil. The thermo-elements are so arranged that the difference between the hot and cold faces can be directly observed with greater accuracy than is possible by measuring the hot and cold face temperatures independently and taking the difference. A diagram of the connections is given in Fig. 6.

(*c*) *Contact resistance between electrode and specimen.*

One fact that became evident at the outset was that the surfaces of the specimens were not perfectly flat, and consequently when tested in an apparatus between perfectly flat metallic plates there was a certain resistance to the heat flow, due to air films at the contact faces.

While it would be possible to eliminate this resistance by amalgamating the metal surfaces, it was deemed advisable to carry out a series of experiments with the material clamped between plain metal plates, since in practice it will be necessary to take account of the surface resistance in any calculations in connection with the design of electrical machinery. A material which has a low resistivity, but whose surfaces are irregular and of an unyielding nature, may not be as useful as one of higher resistivity but with flatter surfaces, for it may happen that in certain thicknesses the total resistance to the heat flow will be higher with the former material than with the latter. Although it is advisable to endeavour to ascertain for each material its true thermal resistivity, some information is necessary on its contact resistance when clamped between two flat metallic plates under definite pressure.

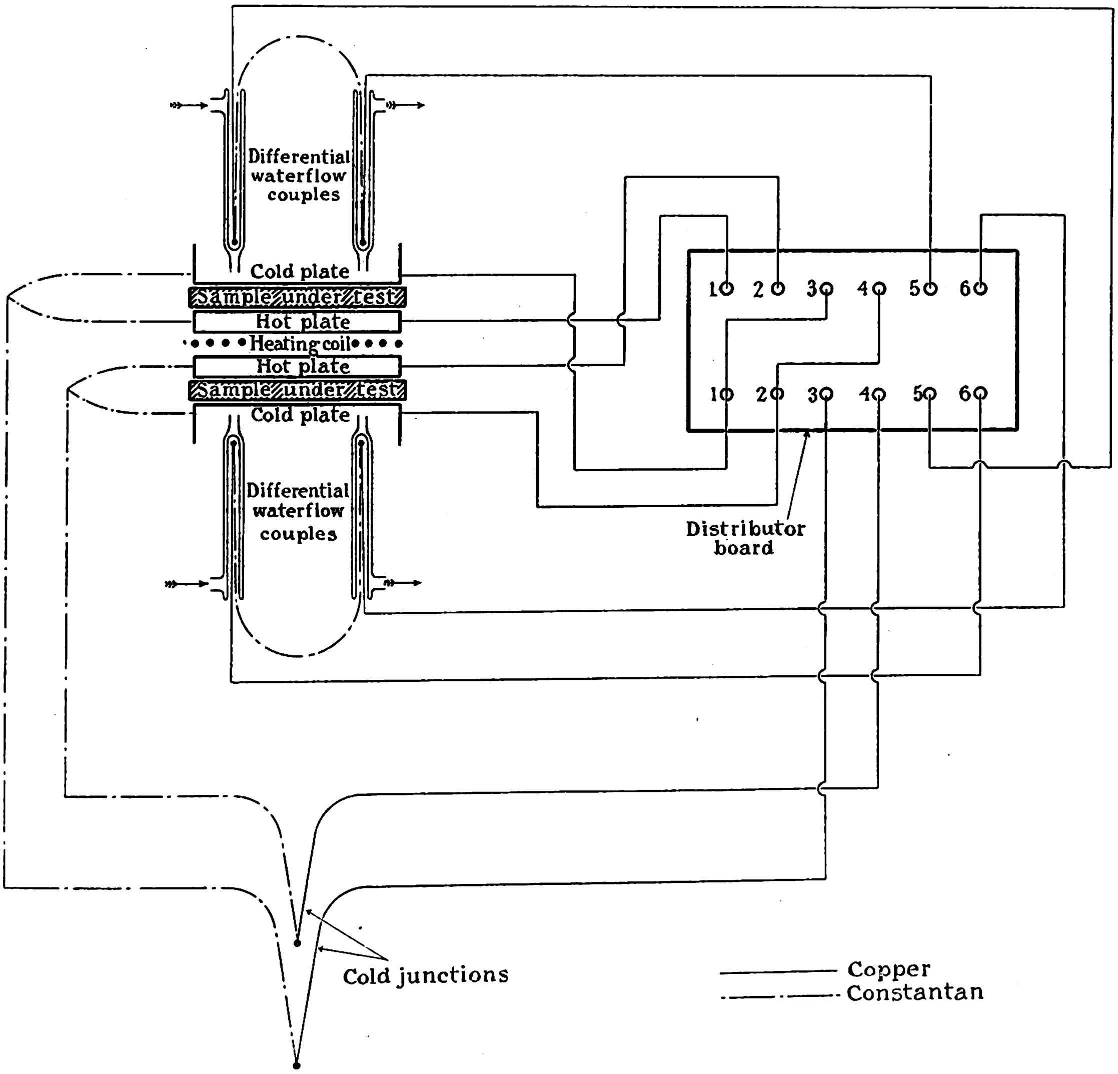

FIG. 6.—Diagram of the connections of Apparatus No. 5.

Another factor which has to be taken into consideration is the variation of the conductivity and the compressibility of the material under load.

In the earlier tests attempts were made to use electrodes of comparatively large area. During some tests with amalgamated copper electrodes measuring 4 in. × 4 in. the following results were obtained:—

The sample of dielectric consisted of two sheets of mica each 0·7 mm in thickness. When the apparatus was set up in the usual manner with a hot plate sandwiched between the two mica slabs it was found that the resistivity K for a pressure of 3·75 lb. per sq. in. was 273, and when the pressure was increased to 75 lb. per sq. in. the resistivity fell to 228.

Measurements of the thickness of the samples at definite points show that they were not absolutely uniform, so it appeared that the amalgamated surfaces were not capable of eliminating the effect of variations in thickness of a sample measuring 16 sq. in. in area. As the result of this experiment much smaller areas were used, and apparatus No. 3 was constructed where the surfaces of contact were only 1·65 sq. in. in area. Messrs. Wiggins & Son very kindly supplied a series of mica samples 1½ in. in diameter and about 1/100th of an inch in thickness, which were uniform in thickness to 1/10 000th of an inch. The results obtained with these micas are quoted in Table 1. Some of the materials tested in apparatus Nos. 1 and 2 were also tested in No. 3. The difference in the results due to the reduction of contact resistance by the mercury was very marked, notably in the case of micafolium (see Table 2).

Some tests were made to ascertain whether the amount

of excess mercury used on the surfaces had an appreciable influence on the results.

The material employed in this investigation was a paper board 0·5 mm in thickness. In the first test the amalgamated copper surfaces were flooded with mercury, test sample inserted, and more mercury added to form two large flattened drops of mercury.

When the surface had been lowered into contact the excess mercury around the edges was removed. In the second test no special care was taken to flood the surfaces; a few drops were placed on both copper surfaces. The experiments were repeated several times, but no measurable difference in the conductivity was observed.

A small correction was always applied for the thermal resistance of the mercury film. This was determined by blank experiments, using a thin sheet of steel instead of the specimen.

(*d*) *Comparison of results obtained with two different forms of apparatus.*

It is of interest to compare data obtained on two forms of apparatus differing very considerably in details of construction, but both employing amalgamated surfaces. An inspection of the data in Table 3 will show the order of the agreement obtained.

When data obtained with and without amalgamation of the surfaces are compared, it is found that good agreement is obtained if the samples are of a slightly compressible nature and tested in thicknesses of the order of 1 to 2 mm.

This is illustrated by the data given in Table 4 obtained with apparatus Nos. 4 and 5 for pressboard, glazed and unglazed.

TABLE 4.

Comparison of Results Obtained with No. 4 Apparatus (Amalgamated) and No. 5 Apparatus (Unamalgamated).

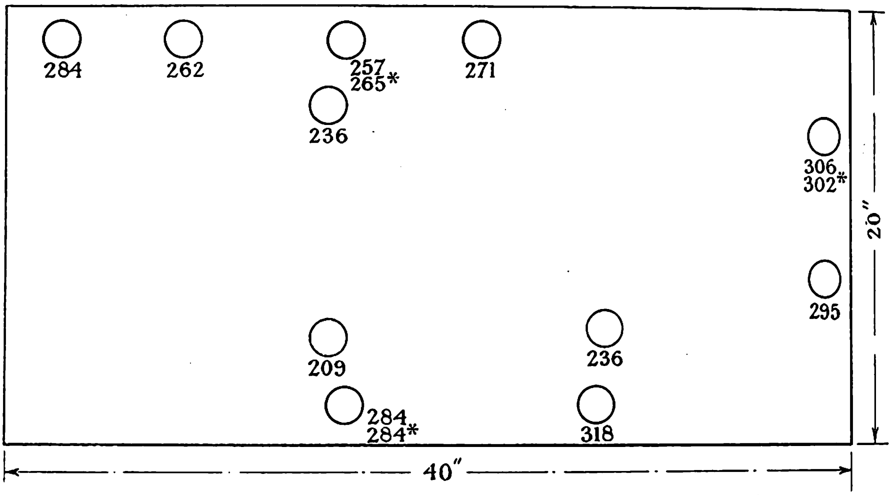
		37·5	516	—	—
		49·2	482	—	—
	10*	21·0	534	24·8	763
		32·5	521	33·8	726
		46·5	505	50·9	670

* These were superimposed layers heated and compressed.

In the case of very thin samples of the order of 0·09 to 0·15 mm (3 to 6 mils), it is questionable whether the true thermal conductivity of the material can be measured accurately by either type of apparatus. Even when the sample is pressed between amalgamated plates it is improbable that perfect thermal contact is effected over the entire area; and as the resistivity of the thin layer of material is small, the residual contact-resistance may be of appreciable magnitude in comparison with the true resistance of the material.

There is indirect evidence to support this view, since



*Denotes repeat reading

FIG. 7.—Variation of thermal resistivity over the area of specimen.

the conductivity of superimposed thin layers increases with the number of layers tested. Reference might be made to Fig. 13, where the results of such experiments are shown graphically.

In the case of hard materials with irregular surfaces the difference between the results obtained with amalgamated and unamalgamated surfaces is considerable, and there is no doubt that the junction from the plain metal surface to the specimen offers appreciable resistance to the heat flow. This is illustrated by the data in Table 5, obtained for a solid block made of ten superimposed layers of micafolium heated and pressed to form a hard sheet.

Thus the general conclusion was that the most satisfactory procedure was to prepare samples from 1 to 2 mm in thickness and test between amalgamated plates. When the material was of such a nature that specimens of this thickness could not be prepared, the test was carried out with unamalgamated plates in apparatus of the type illustrated in Fig. 5.

(*e*) *Variation of the resistivity from point to point over the area of a sheet.*

A sheet of micanite 20 in. by 40 in. was tested at various points of its surface by means of the apparatus illustrated in Fig. 4.

The positions for the test were selected as those showing the widest variation in opacity when the sheet was examined by transmitted light.

The results obtained are shown diagrammatically in Fig. 7.

It will be seen that the variations from point to point in certain areas are very considerable, which is not surprising, taking into consideration the structure of the material.

(*f*) *Measurement of the thickness of the specimens.*

In order to obtain the thickness of the specimens under different loads the apparatus shown in Fig. 8 was constructed.

It consists of a micrometer head clamped to the vertical pillar. The specimen is laid on the table with a disc of steel resting on top of it. The surfaces both of the table and the steel disc are ground accurately

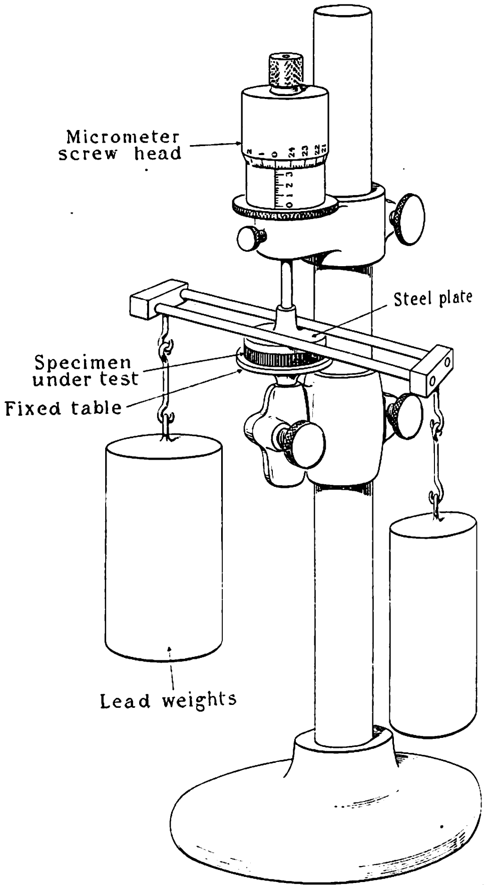


FIG. 8.—Apparatus for measuring decrease of thickness under pressure.

plane. Pressure can be applied by the arrangement of weights shown in the diagram.

The effect of a gradually increasing pressure on the samples for the first time was to produce a permanent deformation, after which loading and unloading gave a reproducible curve (see Fig. 9 and Table 6).

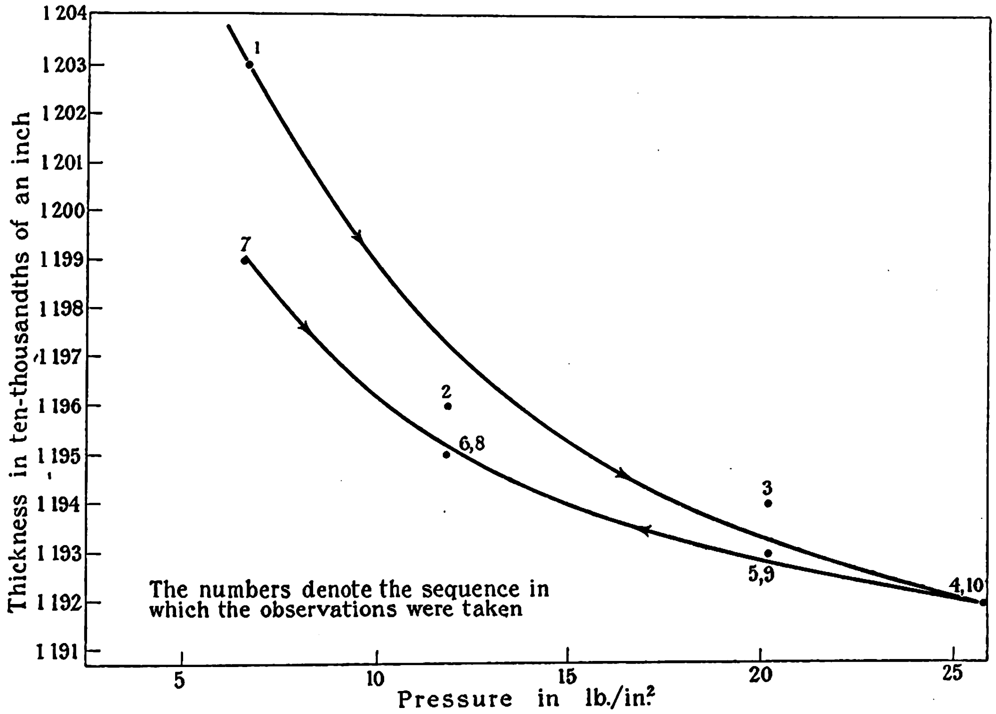

FIG. 9.—Curves showing effect of pressure upon thickness of specimen.

TABLE 6.

Compression Test. Material Tested: Unglazed Grey Pressboard, L. 149.

Pressure, lb. per sq. in.	Thickness in inches	Pressure, lb. per sq. in.	Thickness in inches
6·6	0·1203	11·8	0·1193
11·8	0·1196	6·6	0·1199
20·2	0·1194	11·8	0·1195
25·8	0·1192	20·2	0·1193
20·2	0·1193	25·8	0·1192

(*g*) *Effect of pressure on the thermal conductivity.*

A sample of unglazed grey pressboard was tested under various loads between 8 and 23 lb. per sq. in. The material was of a compressible nature, as the data in Fig. 9 show.

In calculating the resistivity, the appropriate thickness corresponding to each load was taken from Table 6. The results show that there is a small decrease in the thermal resistivity with pressure (see Fig. 10 and Table 7).

(*h*) *Tests on samples taken from sheets of different thickness, but nominally of the same composition.*

A series of samples of glazed and unglazed grey pressboard, varying in thickness from 1/32 in. to ⅛ in., also varnished silk in thicknesses from 3 mil to 6 mil were supplied. The data are summarized in Table 8.

In the case of the unglazed pressboard there appears to be a very slight decrease of resistivity with thickness (see Fig. 11).

The results obtained with the three thicknesses of glazed pressboard are abnormal; the sample taken from L. 152 (⅛ in. in thickness) gives a result 20 per cent less than those obtained for materials labelled L. 150 and L. 151 (1/32 in. and $\frac{1}{16}$ in. respectively). So it appears that the three sheets are not identical in physical properties.*

Sample L. 152 was tested in two different forms of apparatus, amalgamated and unamalgamated, with identical results.

---

* These were supplied as being the same grade of material and from their colour and surface appeared similar. The cause of the anomalous results was traced to the following difference in density:—

1/32 in. .. 1·27; 1/16 in. .. 1·22; ⅛ in. .. 1·08

The low density of the ⅛-in. sample explains the low conductivity. The makers stated that a finer pulp was used in the manufacture of the 1/32-in. and 1/16-in. sheets than for the ⅛-in. material. The same material was used in all three, but the method of manufacture was different.

The four samples of treated silk show a very slight decrease of resistivity with thickness (see Fig. 12), but the change is probably well within the limits of possible variation in the physical properties of the samples, even if prepared from the same raw materials.

(*j*) *Resistivity of a number of superimposed layers of thin material.*

Two samples of treated silk, L. 119 and L. 162, were tested in single and superimposed layers. All the measurements were made at a mean temperature of 21° C.

It will be observed from an inspection of Fig. 13 that the apparent resistivity decreases with increasing number of layers, but probably tends asymptotically to a constant value.

When a number of thicknesses of the treated silk are superimposed the layers tend to bed into each other, and thus effect good contact at the interfaces, so that the decrease in resistivity with increasing thickness of the test sample may be due to the contact resistance at the metal-specimen surfaces becoming relatively less important in comparison with the total resistance of the sample. That there is appreciable contact resistance at the contact surfaces is shown by the difference between the unamalgamated- and amalgamated-surface curves in Fig. 13.

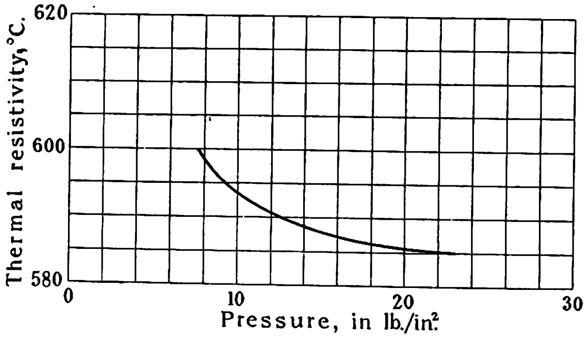

FIG. 10.—Curve showing influence of pressure upon thermal resistivity of unglazed pressboard.

It is thus seen that with a material like treated silk, even when tested between well-amalgamated plates, it is not possible to effect perfect thermal contact.

TABLE 7.

Effect of Pressure on the Thermal Resistivity. Apparatus No. 5 (Unamalgamated Surfaces).

Material	Pressure, lb. per sq. in.	Mean temperature, ° C.	Thickness of sample, in.	Thermal resistivity K

	23·0	26·4	0·1192	583

(*k*) *Effect of temperature and pressure on the thermal resistivity of two samples of varnished cloth.*

NOTE.—The object of the investigation described below was to determine, under certain conditions, the effect of temperature and pressure on the transmission of heat through two sheets of varnished cloth, which were labelled L. 600 and L. 601 respectively. This did not form part of the main investigation, but was carried out at the N.P.L. at a later date.

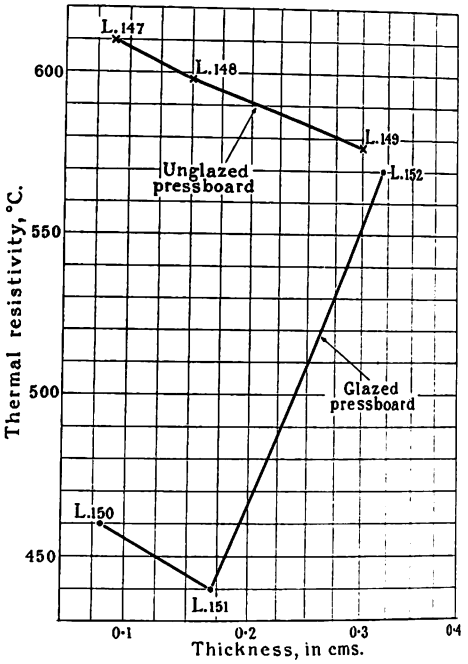

FIG. 11.—Variation of thermal resistivity with thickness of specimen (pressboard).

Method of experiment.

The method employed was identical in principle with that adopted in the main investigation into the resistivity of dielectrics, which forms the subject of this

TABLE 8.

Single Layers of Various Thickness. Apparatus Nos. 4 and 5. Pressure, 21 lb. per Square Inch.

The thick samples were tested in Apparatus No. 5, and the thin ones in No. 4. Table 4 on page 1320 shows that, subject to the reservations made in clause (*d*) (pages 1311 and 1312), test results obtained on the two forms of apparatus are comparable.

report. Six discs of each material were cut, and arranged so that three were piled on each side of an electrically-heated plate of the same area as the samples. The whole was then clamped between two cold plates maintained at the same temperature. A measurement of the energy input into the hot plate and of the temperature-difference between the hot and cold plates, subject to a small correction for the lateral escape of heat, served to give the thermal resistivity.

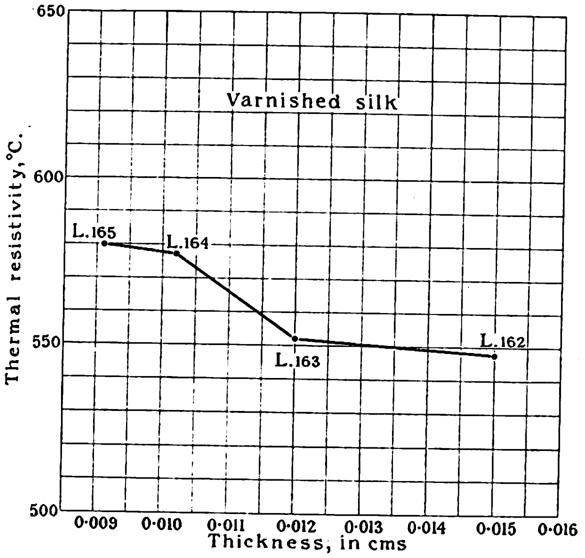

FIG. 12.—Variation of thermal resistivity with thickness of specimen (varnished silk).

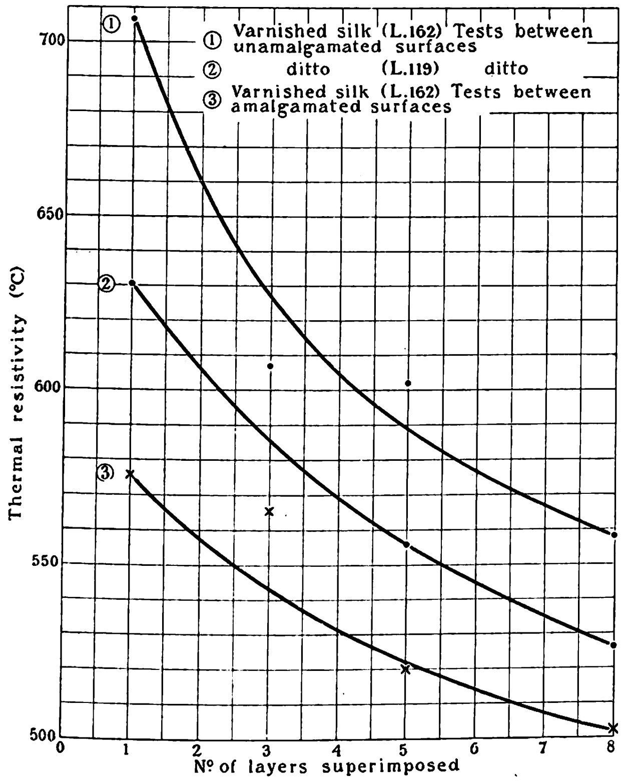

FIG. 13.—Curves showing decrease of thermal resistivity with number of layers of laminated material.

The hot plate consisted of a flat heating coil insulated with mica and clamped between brass discs.

The following procedure was adopted for the test on each specimen:—

The resistivity was measured at a series of increasing pressures for a mean temperature of 20° C.

When the maximum load had been reached the resistivity was measured at various mean temperatures up to 90° C. The resistivity was finally re-determined at a mean temperature of 20° C. An indication was thus obtained of the effect of high temperatures on the thermal resistivity.

Results of Experiments.

The results of the experiments are set out in Tables 12 to 15.

TABLE 12.

Variation of Thermal Resistivity with Pressure. Varnished Cloth: Sheet labelled L. 600. At a mean Temperature of 20° C.

20	0·000535	445

It will be observed that the effect of pressure on the resistivity is less pronounced in the case of L. 601 than in the case of L. 600. This may be related to the fact that the surface of L. 600 is rougher than that of L. 601.

The resistivity is permanently reduced after exposure to a temperature of 90° C., and the repeat value at lower temperatures is in close agreement with that found at the highest temperature. This was confirmed in an independent test when another specimen of the material was heated to a maximum temperature of 75° C., the subsequent determination at 20° C. agreeing with the value obtained at 75° C.

(*l*) *Shape of the test specimen.*

Another factor studied was the shape of the test specimen. It was not always convenient to cut the specimen in the form of circular discs of the exact diameter of the copper rods, so larger-size specimens of rectangular shape were generally used. A test was made with one of these large specimens, and the experiment repeated after the specimen had been cut down to a circular disc of the exact diameter of the copper rods. The differences in the values obtained for the resistivities were quite negligible, being well within the limits of the experimental error. Hence the practice of using reasonably large-size plates is legitimate.

(*m*) *Results obtained during the main series of tests on materials studied in sheet form.*

The results of the preliminary tests are recorded in Tables 1, 9, and 10. It must be remembered, however, that these results are not strictly comparable, as those recorded in Tables 9 and 10 are "apparent" resistivities, contact resistance being included. The data in Table 1 are "true" resistivities obtained by experiments in which the contact faces were amalgamated. The small size of the mica specimens, 1½ in. in diameter, prevented tests being made in apparatus Nos. 1 and 2, which require specimens at least 1¾ in. in diameter.

Table 11 summarizes the data obtained during the determination of the true thermal resistivities of the materials included in the investigation.

It will be observed that each class comprises substances differing very considerably in thermal resistivity. The sixteen samples of fibre range in resistivity from 478 to 266.

The sample of whalebone gave the lowest resistivity of all the materials studied, the value being about 10 per cent lower than that for the best fibre.

The five samples of treated silk have a high apparent resistivity which may be in part due to residual contact resistance.

Part II.

A STUDY OF THE THERMAL RESISTIVITY OF SOLID DIELECTRICS WHEN APPLIED ON TO BARS BY THE USUAL SHOP PROCESSES OF WRAPPING.

(*a*) *General.*

The preceding section of the report has been concerned with the thermal resistivity of a number of materials tested between flat plates. Frequently it is not possible to apply the results directly to the conditions under which the materials are used in electrical machinery and apparatus, owing to factors which may complicate the estimation of heat flow. Examples of such factors are the shape of the body to be insulated, the effects of air-gaps and slots, and the conditions of fixing or winding the insulating medium. Consequently it was considered desirable to investigate the thermal resistivity of selected materials after they had been applied by the usual shop processes to conductors of such shape and dimensions as are employed in practice.

This investigation was confined to the materials and processes used particularly for the insulation of the slot portions of machine windings, such as turbo-alternator stators,* as the heat flow through the insulation of these parts is a matter of considerable importance in the design of such windings.

Preliminary experiments were made with bars of rectangular and circular sections insulated with micafolium (not pressed), using an apparatus employing air cooling, the insulation on the bars not being supported.

For the main investigation, however, bars insulated with micafolium and mica tape were tested by two different methods: one similar to that used in the preliminary tests, and the other designed to simulate as closely as possible the conditions existing in the slot of a machine. In the latter case the bar was held between water-cooled clamping plates, so that the insulation was prevented from swelling when heated. Tests were also made by this method, using different clamping pressures applied to the water-cooled plates, to determine the effect of variations in these pressures on the thermal resistivity of the insulations.

The insulation on the bars was applied by the usual shop processes, e.g. wrapping, hot pressing, etc., and some of the bars were tested before and after an artificial "ageing" at a temperature of 100° C., to determine the effect of this treatment on the thermal resistivity values.

(*b*) *Preliminary tests on bars of various section insulated with micafolium.*

The first case taken was that of a rectangular bar insulated with a wrapping of micafolium. Imitation stator bars were constructed; one, by joining together, face to face, two flat bars of copper in which longitudinal grooves had been milled, the other, built up of flat strips into a box form. The hollow bars thus formed were slightly rounded along the edges, in accordance with the usual practice, and were wrapped with micafolium to a thickness of 0·2 cm.

---

* Further investigations are in hand on the thermal resistivity of insulation on bars representing the materials and methods used on "end-windings" of machines.

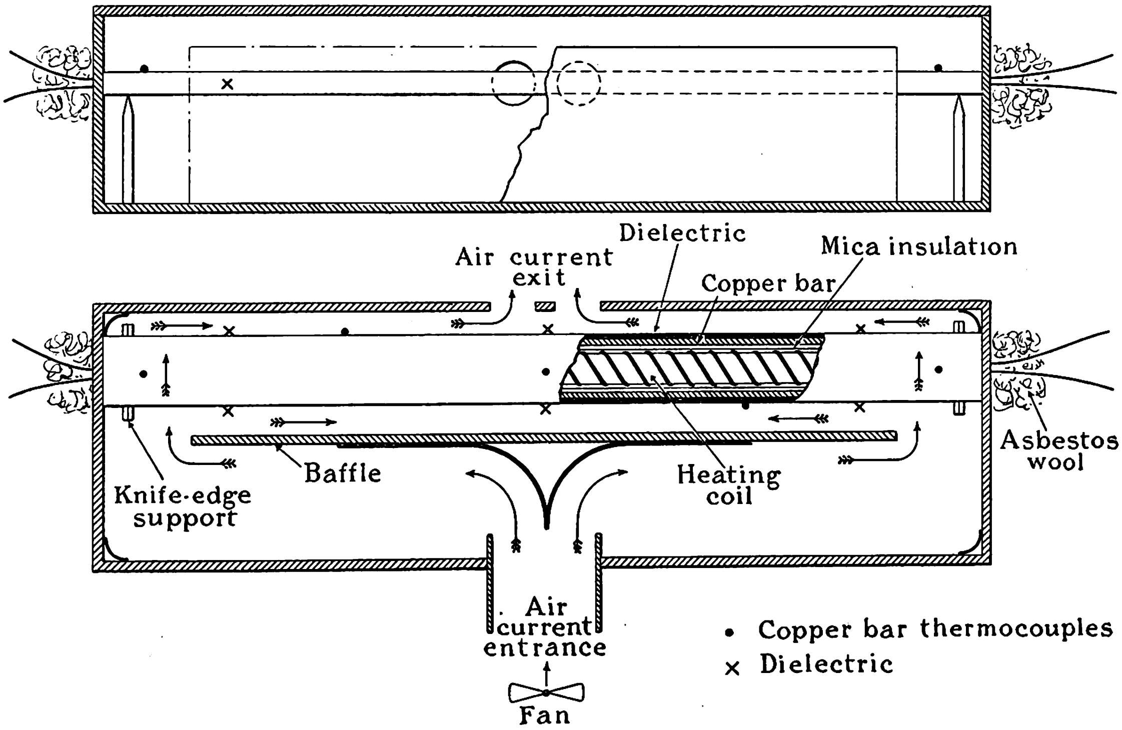

Fig. 14.—Apparatus for the study of the thermal resistivity of insulated copper bars.

The arrangements for carrying out a test were as follows:—

A long heating coil of nichrome wire or strip was inserted into the interior of the bar. A series of thermocouples pegged into the copper or fixed to the outside of the insulation served to give the temperature distribution of the hot and cold surfaces. To facilitate the temperature measurement of the cold surface the outside of the insulation was sprayed with zinc. In order to obtain a sufficiently large gradient of temperature through the insulation, the bar was placed in an enclosure and air was blown on the surface of the specimen. A section and plan of the apparatus are shown in Fig. 14.

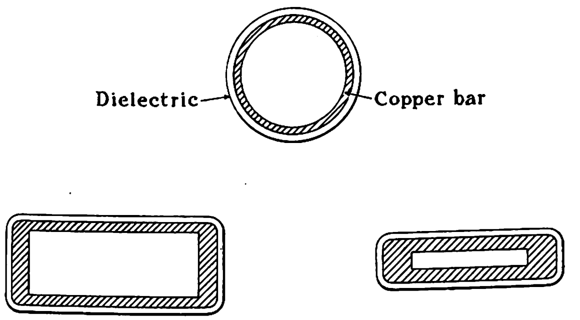

Fig. 15.—Sections of the insulated copper bars used in test.

Experiments were made on two bars, each a metre long and of cross-sections $5 \times 1\cdot2$ cm and $6\cdot1 \times 2\cdot5$ cm respectively. The micafolium was wrapped tightly on the bars, but was not pressed. For purposes of comparison a cylindrical bar wrapped in the same way with micafolium was also tested; the thickness of the insulation in all cases was about 0·2 cm. The sections of the bars are shown in Fig. 15.

In conducting an experiment the energy required to maintain a steady difference in temperature was determined. If E is the energy and T the temperature-difference, then in order to obtain the resistivity K it is necessary to know the value of the constant S in the equation:—

$$E = \frac{S \times T}{K}$$

The constant S depends entirely on the dimensions, and has been called the " shape factor."

The evaluation of the shape factor in the case of a bar of a rectangular section does not admit of exact mathematical treatment, but a graphical solution of the problem is given in Appendix I. The assumptions there made are that the insulator is of uniform resistivity and that the inner and outer surfaces of the insulation are isothermals.

Two cases are considered, namely, that in which the outer surfaces of the bar and insulation are rectangular in section, and that in which the edges of the bar and insulation are rounded.

It is estimated that these cases give almost identical results, the shape factor being approximately:—

$$S = \left(\frac{2(b+c)}{t} + 2\cdot2\right)l \quad . \quad . \quad . \quad (1)$$

where l, b and c are respectively the length, breadth, and depth of the bar and t the thickness of the insulation. To appreciate the significance of formula (1) it may be compared with that given by a flat sheet of material of thickness t and of area equal to the inner surface of the insulation on the bar, or, alternatively, the mean of the inner and outer surfaces of the insulation on the bar.

The shape factors of these two cases would be respectively:—

$$S = \left(\frac{2(b+c)}{t}\right)l \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$S = \left(\frac{2(b+c)}{t} + 4\right)l \quad . \quad . \quad . \quad . \quad (3)$$

It will be seen that (1) lies between (2) and (3).

Reverting to the experiments on the bars, the temperature measurements indicated that there was considerable gradient in temperature from the centres to the ends of the bars. The temperatures of the surfaces of the insulation were more uniform. Under these circumstances it was only possible to arrive at an approximate estimation of the mean temperature gradient through the insulation. The results obtained with the three bars are given in Table 16 and are plotted in Fig. 16. For purposes of comparison the resistivity of small specimens of micafolium were also determined with apparatus Nos. 4 and 5. A single layer as well as a sample made from ten superimposed layers of material pressed together and heated at 140° C. for 5 hours was tested. The values are given in Table 17 and in Fig. 16.

TABLE 16.

Summary of Results on Copper Bars Insulated with Micafolium (Unpressed). Bars not Clamped during Tests.

Description of copper bars	Mean thickness of insulation, in cm	Mean temperature of hot surface, ° C.	Mean temperature of cold surface, ° C.	Mean temperature-difference, deg. C.	Thermal resistivity K
Small rectangular bar	0·204	42·0	32·3	9·7	920

		83·0	53·9	29·1	720
		80·0	52·0	28·0	750*

* Denotes repeat reading.

Where the thickness of the insulation is small as compared with the other dimensions the differences between the above formulæ are unimportant. Thus, in the case of the bar used in the present experiments, which had a cross-section 5 × 1·2 cm, the insulation being 0·2 cm thick, formulæ (2) and (3) would give a result within about 3 per cent of that given by formula (1).

For the cylindrical bar the shape factor is:—

$$S = \frac{2\pi l}{\log_e \dfrac{b}{a}} = \frac{2 \cdot 73 l}{\log_{10} \dfrac{b}{a}}$$

b and a being the outer and inner diameters. As in the case of the rectangular bar, the treatment of the insulation as flat and of area equal to that of the inner surface of the insulation on the bar, or of the mean of the inner and outer surfaces, does not introduce a large error.

Whilst the experiments on the bars were regarded as being merely of a preliminary character, the following conclusions may be drawn:—

It will be noticed that the lowest apparent resistivity is given by the apparatus with amalgamated surfaces, and that the values obtained with the unamalgamated surfaces and the round bar are in fair agreement and are less than those given by the rectangular bars. The explanation of this order of values would appear to lie in the fact that the resistivity of a number of layers of a material like micafolium depends, to a considerable extent, on the closeness of the contact between the successive surfaces through which the heat has to pass. The greatest flow of heat would be expected where the layers are kept in contact by pressure and the bounding surfaces are in contact with mercury films; while, with an unsupported rectangular bar (as distinct from one tightly wedged in a slot as in service), good contact between the layers would only be expected in the neighbourhood of the corners, and the heat flow would therefore be less than in the other cases, including that of the cylindrical bar. It was noticeable that after the experiments the insulation on the rectangular bars could be depressed by the pressure of the fingers on the flat surfaces, thus showing that air-gaps were present.

TABLE 17.

Summary of Results on Micafolium Tested with Apparatus No. 4 (Amalgamated) and Apparatus No. 5 (Unamalgamated).

Number of thicknesses	Thickness, in cm, of sample tested	Mean temperature, ° C.	Thermal resistivity K
No. 4 Apparatus (amalgamated surfaces).			
Single layer	0·018	22·5	570
		37·5	516
		49·2	482
10 superimposed layers	0·091	21·0	534
		32·5	521
		46·5	505
No. 5 Apparatus (unamalgamated surfaces).			
10 superimposed layers	0·091	24·8	763
		33·8	726
		50·9	670

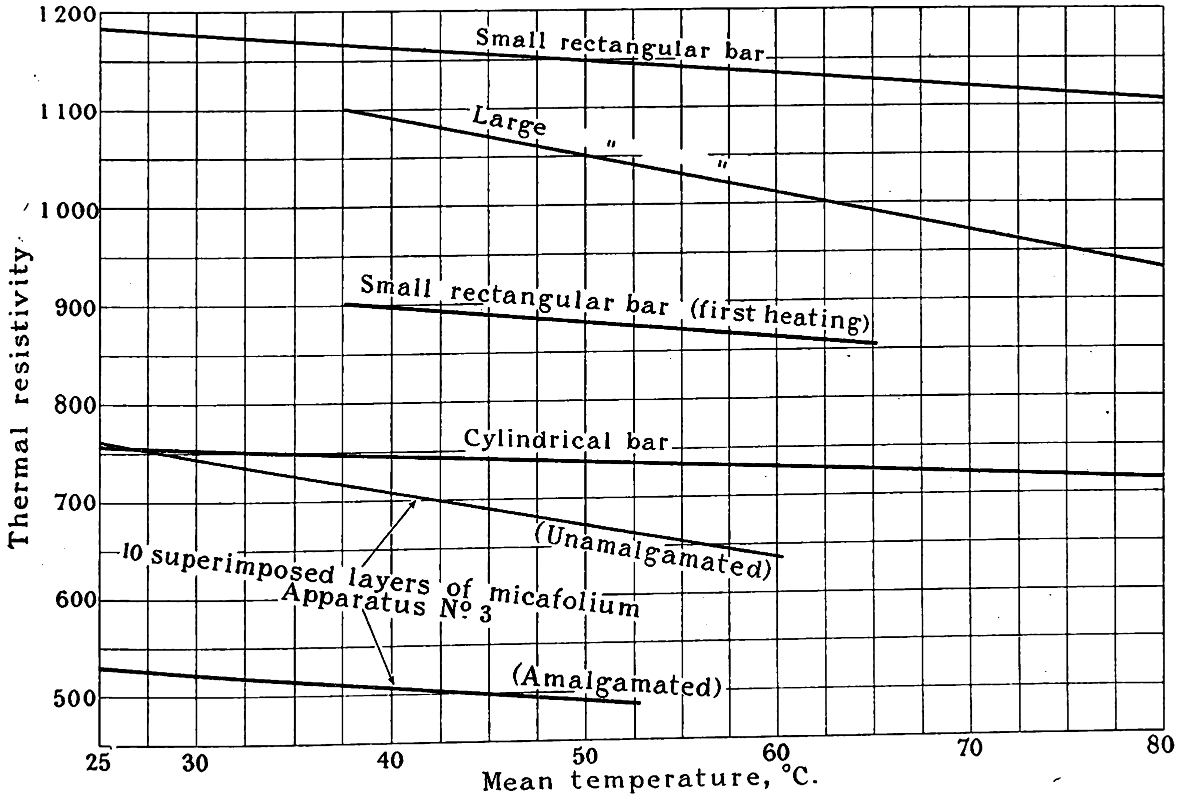

FIG. 16.—Thermal resistivity values from Tables 16 and 17.

It is also significant that the results obtained for the small rectangular bar on first heating were decidedly lower than those subsequently obtained, suggesting that the insulation slackened off when raised to higher temperatures. No such effect was observed in the case of the round bar.

(c) *Main series of tests on bars insulated with micafolium and mica tape.*

The object of the investigation was to determine the effective resistivity of wrappings of micafolium and mica tape on turbo stator bars under conditions similar to those prevailing in actual practice. For this purpose the thermal resistivity has been measured after the application of the insulation to the stator bar.

Two investigations were made, using the following methods of testing:—

Method (I)—Bars unclamped—air-cooled.

Method (II)—Bars clamped between water-cooled plates.

(i) *Method (I)—Bars Unclamped—Air-cooled.*

General.

In this investigation, tests were made by means of an apparatus similar to that used for the preliminary experiments, i.e. the bars were not clamped during the test.

In the case of micafolium, since two distinct processes are involved, namely, " machine-wrapping " and " hot-pressing," the value of the resistivity was determined after each process. Both materials were then artificially " aged " by heating for a week at a temperature of 100° C., the bars on which they were wound being clamped during this period between iron plates so as to correspond to the case of a stator bar wedged in the slot of an actual machine. The effect of the " ageing " process was gauged by a re-determination of the resistivity. It should be added that, since it is usual to apply a layer of cotton tape on the outside of the mica-tape wrapping, the resistivity after first winding was determined with and without this layer. It was hoped also to determine the effect of " ageing " the cotton-tape layer, but as time and funds did not permit, the effect of " ageing " the mica tape only was investigated.

The following determinations of thermal resistivity were thus made on the micafolium and mica tape:—

Micafolium.

After machine-wrapping, after hot-pressing and after " ageing."

Mica tape.

After wrapping, with and without the layer of cotton tape, and after " ageing " without the layer of cotton tape.

The bars were insulated by standard works processes in members' works. The ageing was also carried out by the members, who kindly co-operated by insulating the bars.

Method of experiment.

The method of test used was developed from the method employed for the preliminary experiments on stator bars described in (*a*) above. As in the previous tests, a hollow bar was made up by joining together thick strips of copper so that the outer dimensions were typical of those of a stator bar. The length of the bars used was 60 cm, the cross-section was 6 × 1·6 cm, and the thickness of the test insulation about 3 mm. A section of the bar is shown in Fig. 17. The hollow interior of the bar was filled by a flat heating coil consisting of nichrome wire wound on micanite and insulated externally by micanite.

For the purpose of determining the resistivity of the insulation the bar was placed transversely in a steady stream of air which removed the heat dissipated in the internal heating coil. When steady conditions of temperature have been reached, a measurement of the energy supplied to the coil, of the temperatures of the inner and outer surfaces of the insulation, and of the dimensions of the insulation, suffices to give the resistivity. Thus, if Q is the rate of heat supply, T the temperature-difference between the outer and inner surfaces of the insulation whose resistivity is K, then:—

$$Q = \frac{ST}{K}$$

where S is a constant depending on the shape and dimensions of the insulation. As explained in section (*a*) above, the following solution for the constant S given in Appendix I has been used as representing the best available approximation to the conditions of the experiment:—

$$S = \left(\frac{2\,(b+c)}{t} + 2\cdot 2\right)l$$

where l, b and c are respectively the length, breadth and depth of the bar, and t the thickness of the insulation.

Of the quantities involved in obtaining the thermal resistivity only the measurement of the thickness t and the temperature-difference T presented any difficulty. The thickness was obtained by measuring with a micrometer the overall thickness of the bar with and without the insulation. It was estimated that the measurement of thickness could not be made better than to the nearest 0·1 mm on a total of 3 mm.

As regards the measurement of the temperature-difference, the difficulties in dealing with materials in the form used in the present experiments are very considerable. The inner temperature was taken to be that of the copper bar and was measured by means of a series of copper-constantan couples pegged into it at various points along its length. By a suitable adjustment, by means of vanes, of the distribution of the air flow, a practically uniform temperature along the whole length of the bar was obtained, the thermo-couples giving readings agreeing to about 0·2 deg. C.

For measuring the temperature of the outer surface the use of thermo-couples attached to copper discs was first tried, but was abandoned as, owing to irregularities in the distribution of temperature, a large number would have been required to obtain the mean value of the temperature. The thermometric device finally used for the purpose was a platinum resistance thermometer consisting of a wire 0·2 mm in diameter, 6·5 metres long, and about 40 ohms in resistance, which was wound in a spiral along the outer surface of the insulation, the whole being cased in a wrapping of rubber tape. A plan of the apparatus is shown in Fig. 17.

Measurements of the resistance of the thermometer were obtained by comparing the volt-drop, for a constant current of the order of 100 micro-amperes, on the thermometer and a standard resistance arranged in series with it. The resistance thermometer was used differentially as follows:—

It was first calibrated in terms of the thermo-couples attached to the bar by comparing their readings when the bar was encased in a thick layer of cotton wool about 4 in. deep and maintained at a constant temperature by means of the internal heating coil. Under these conditions the temperature gradient through the thin layer of micafolium or mica tape was assumed to be negligible in comparison with that induced by placing the bar, without the protecting layer of cotton wool, in a rapid current of air. The difference in the readings of the resistance thermometer from those of the thermocouples under the conditions of the actual experiment was taken to give the temperature-difference induced by the air current in the test layer of micafolium or mica tape.

It may be mentioned that alternative and doubtless more precise methods were considered for dealing with the problem of temperature measurement and of cooling the external surface, but the method described above was adopted as probably giving a close approximation to the desired conditions for the minimum expenditure of time and money.

Results obtained by Method I.

The results of the experiments are set out in Table 18, and the values are shown graphically in Fig. 18.

For purposes of comparison, two sets of values which were obtained in previous experiments for a number of superimposed layers of micafolium have also been plotted in Fig. 18.

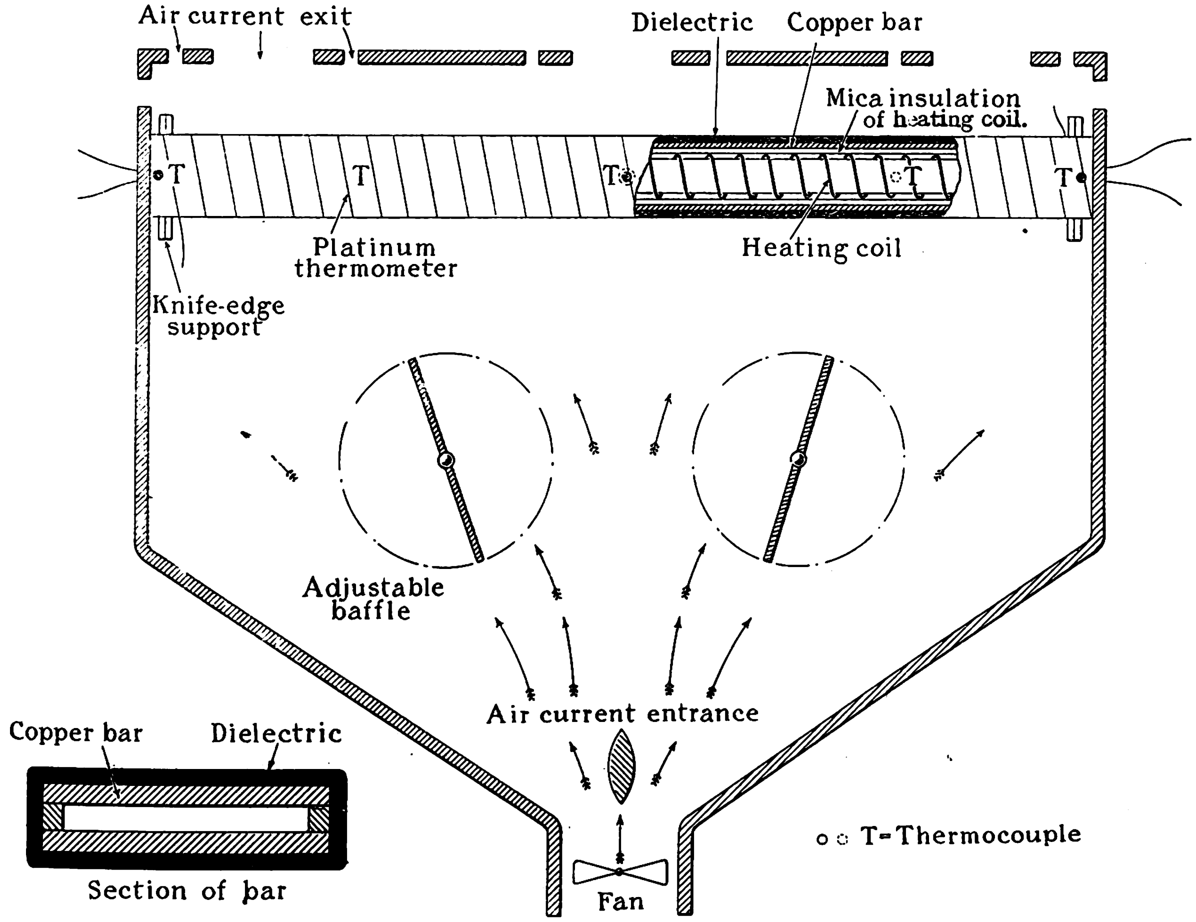

FIG. 17.—Apparatus for the determination of the thermal resistivity of insulated bars—unclamped.

In the previous experiments the specimen sheets of micafolium were clamped between flat copper plates, the surfaces of which in one case were amalgamated and in the other unamalgamated. It will be seen that the effect of improving the surface contact by amalgamation has been to lower the resistivity from about 760 to 530. This is ascribed to the irregular nature of the surface.

In the present experiments a big decrease in the resistivity of the micafolium is produced by the hot-pressing process, due, presumably, to the improvement in contact between the successive layers by the elimination of air films. On the other hand the subsequent "ageing" process has produced an apparent rise in resistivity of the order of 20 per cent. The reason for this result is not obvious, since the material has been subject to great pressure in the process of "ageing." However, it should be mentioned that the combined effect of the pressure and a temperature of 100° C. has been to squeeze out a considerable amount of shellac.

In the case of the mica tape experiment the resistivity with and without the layer of cotton tape is somewhat more than that of the micafolium in the first stage (hand-wrapped). The material in the first state was noticeably springy, indicating imperfect contact between successive layers. The pressures involved in "ageing" have evidently improved the contact since the material shows a decrease in resistivity of the order of 40 per cent.

TABLE 18.

Thermal Resistivity of Stator Bars Tested Unclamped—Air Cooled.

† Denotes repeat reading.

In considering the results obtained during the tests on the insulated stator bars it is important to note that during the tests the insulation on the bars was not subjected to any external pressure, as always occurs under service conditions. In considering the results of the preliminary series of tests (see page 1330) it was recorded that the resistivity of a number of layers of a material like micafolium depends to a considerable extent on the closeness of the contact between the successive surfaces through which the heat has to pass, and that the tests on bars on rectangular section had shown that, unless the bar was subjected to pressure, good contact between the layers could only be expected in the neighbourhood of the corners.

In the tests carried out by Method II, this feature has been recognized and provision has been made for the determination of the thermal resistivity of insulated stator bars, the specimens being clamped as in the case of insulated bars tightly wedged in the slots of a machine.

(ii) *Method (II)—Bars Clamped between Water-cooled Plates.**

The tests in this series were carried out with the bars tightly clamped between water-cooled plates, the pressure applied being approximately that which it was considered would be obtained in the slot of a machine.

---

* This part of the investigation was carried out by the British Thomson-Houston Co., Ltd.

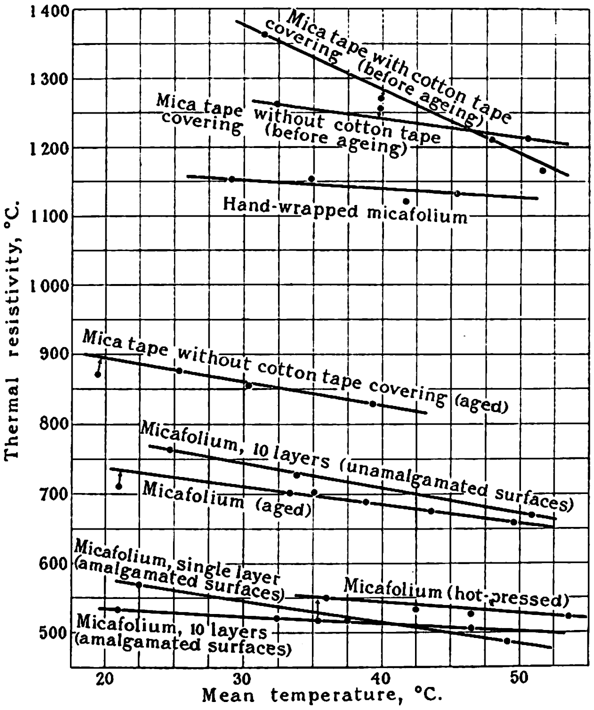

FIG. 18.—Curves showing the variation of thermal resistivity with temperature.—Method I.

The bars were rectangular, the dimensions being similar to those of a conductor used in regular windings. Thermal resistivity tests were made on bars insulated with paper-backed mica tape, and also on a bar insulated with micafolium.

In order to determine the effect of variations in the pressure applied to the clamping plates, on the thermal resistivity results and with a view to correlating the results obtained in this investigation with those obtained by Method I, further tests were carried out using different pressures applied to the clamping plates. These pressures were determined by means of calibrated springs fixed between the clamping plates and the screws.

Description of Insulated Bars.

The bars used for these tests were hollow and of rectangular section, built up of flat strips of copper, the outside dimensions being 2·438 in. × 0·75 in. and 19 in. long. Thermo-couples were attached to the outside surface of the bars in the positions shown in Fig. 19, and an electrical heating unit was fixed inside the bar.

The insulation on the bars was applied by the usual shop processes, including wrapping and hot pressing, etc. In the case of the mica-tape insulated bars, the insulation included an outside layer of cotton tape, the thermal resistivity measurements being made with this tape in position.

Description of Apparatus.

The test bar was held between four copper cooling plates, cooling water being circulated through the latter. Pressure was applied to the clamping plates by means of screws, and for the tests carried out to determine the effect of varying this pressure special clamps were used in which calibrated springs were inserted between the clamping screws and the plates, in order that the applied pressure could be determined.

In order to measure the temperature-drop across the insulation, thermo-couples were also fixed on the surfaces of the clamping plates adjacent to the insulation, and in positions corresponding with the thermo-couples on the insulated bar (see Fig. 19). The thermo-couples consisted of Eureka wires soldered to the copper bars, these being connected as shown in Fig. 20. The temperature-drop across the insulation was obtained by balancing the e.m.f.'s of the external junctions against

Method of Test.

(*a*) *Bars tightly clamped.*—In the first series of tests, the results of which are given in Table 19, the bars were clamped by means of the clamping screws. They were clamped tightly so as to get a pressure on the insulation which was considered to be equivalent to that obtaining in the slot of a machine. The bars were heated by supplying current to the heating units, the power supplied to the units being measured and adjusted to values which would give various temperature-differences across the insulation, the thermal resistivity being determined from the temperature measurements made under these various conditions.

(*b*) *Tests for effect of variation of clamping pressure.*—In the tests made on the bars to determine the effect of variation of clamping pressure on thermal resistivity, two sets of readings were made under each pressure, the method of test being otherwise as described above. The results of these tests are given in Table 20, in which corresponding figures taken from Table 19 are also included.

Determination of Thermal Resistivity K.

In order to fall into line with the way in which the data is to be used in practical calculations, the thermal resistivity, expressed by symbol K, is defined as the ratio of the temperature-difference (expressed in deg. C.) across opposite faces of a centimetre cube, to the resulting heat flow (expressed in watts).

If, therefore, in an experiment on a particular sample:—

e is the energy transferred through the insulation in watts,
T is the observed temperature-difference in degrees Centigrade,
t is the thickness of the insulation,
L is the length of the sample,
C is the equivalent circumference,

then the resistivity K is given by the expression:—

$$\frac{T \times L \times C}{e \times t}$$

The only quantity which cannot be directly measured is the equivalent circumference of the sample, as a complication arises owing to the peculiar distribution of heat flow at the corner. However, if

b = depth of bar upon which the insulation is formed, and
w = the corresponding width,

then the equivalent circumference may be taken as:—

$$2(b + w + 1{\cdot}1t)$$

The value of the thermal resistivity K is therefore given by the expression:—

$$K = \frac{T \times L}{e \times t} \times 2(b + w + 1{\cdot}1t)$$

Results obtained by Method II.

From the results given in Tables 19 and 20 curves were plotted from which the values corresponding to an average insulation temperature of 35°C. were interpolated. These figures are given in Tables 21 and 22, in which are also included the values obtained by the

National Physical Laboratory. These values are also plotted in Figs. 21 and 22, from which the relationship between thermal resistivity and applied pressure can be readily seen.

ably higher than that of micafolium. The present investigation demonstrates that there is little difference between the thermal resistivities of the two wrappings under service conditions.

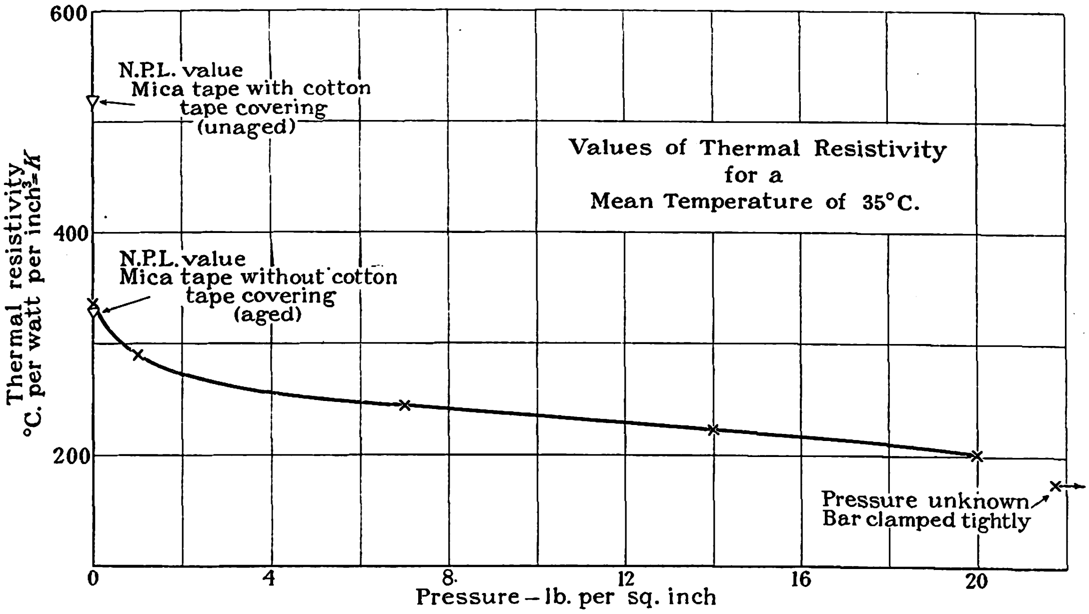

FIG. 21.—Showing the influence of mechanical pressure on the thermal resistivity of mica tape.

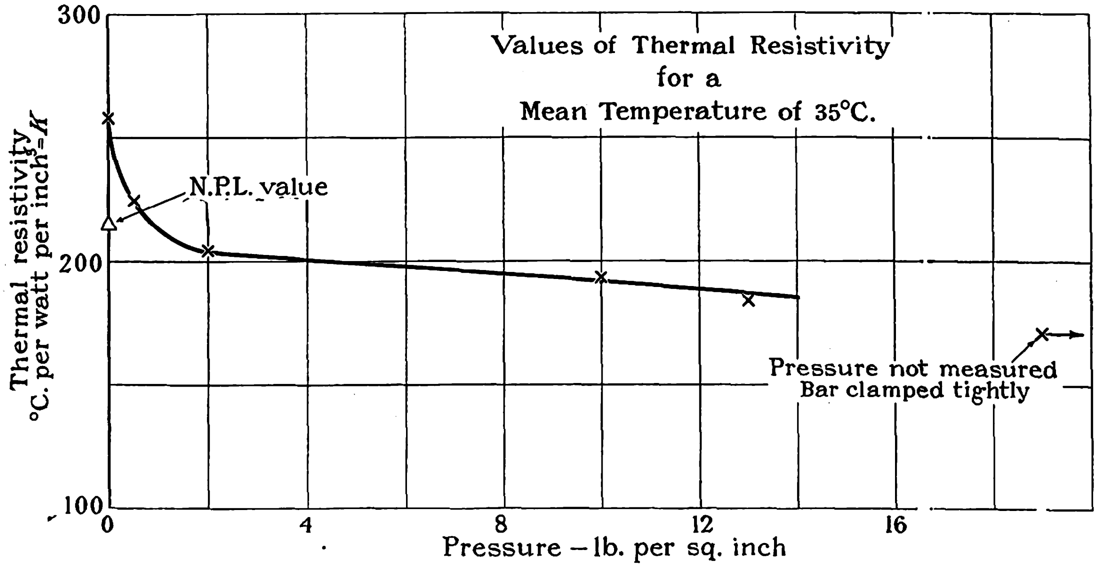

FIG. 22.—Showing the influence of mechanical pressure on the thermal resistivity of micafolium.

The thermal resistivity of both mica tape and micafolium wrapped on bars is found to be lower when the insulation is supported between plates, as in the slot of a machine, than when measured without support or clamping means.

Conclusions.

The previous investigation (Method I) showed that with the insulation unsupported during the test, the mica tape wrapping had a thermal resistivity consider-

Part III.

A STUDY OF THE THERMAL RESISTIVITY OF SHEET-STEEL STAMPINGS TRANSVERSE TO THE LAMINATIONS.

(*a*) *General.*

The object of the investigation was to determine under certain conditions the effect of pressure and temperature on the transmission of heat through various types of stampings as used in electrical machines. A number of firms were invited to submit specimens, the description of which, together with the identification numbers used in this report, are indicated below, viz.:—

FIG. 23.—Apparatus for the determination of the thermal resistivity of sheet-steel stampings.

Specimens Nos. 1 and 2 had the insulating medium applied on both sides of the stamping, and the remaining specimens on one side only.

(*b*) *Method of test.*

The methods used for determining the resistivity were similar in principle to those adopted in the other investigations on the thermal resistivity of dielectrics. Two flat specimens of the material under test were arranged one on each side of an electrically-heated plate of the same area, and the whole was then clamped between two cold plates maintained at a constant temperature by water circulation. A measurement of the energy input into the hot plate and of the temperature-difference between the hot and cold plates, subject to a small correction for the lateral escape of heat, serves to give the thermal resistivity.

The details of the apparatus are shown in Fig. 23. The hot plate consisted of a flat heating coil insulated with mica and clamped between brass discs. The stampings, in two sets of fifteen, were arranged one set on each side of the hot plate, and were held between two water-cooled boxes, which in turn were clamped between heavy iron plates. The pressure was applied by means of springs previously calibrated, and shown in Fig. 23. These were compressed by nuts bearing on the top plate and working on rods which were anchored to the heavy base, and allowed of pressures up to 200 lb. per square inch on the test specimens, which were 3 in. in diameter. The thickness of the specimens was found to vary only slightly with pressure, the maximum change being of the order of 3 per cent.

The following procedure was adopted for the test on each specimen:—The resistivity was measured at a series of increasing pressures for a temperature-difference of about 20 deg. C. When the maximum load had been reached the resistivity was measured for a temperature-difference of 60 deg. C., as well as 20 deg. C. Reverting to a temperature-difference of 20 deg. C. the resistivity was then determined for a series of decreasing pressures. Measurements were thus made for a temperature-difference of about 20 deg. C.—corresponding to a mean temperature of the specimen of 25 deg. C.—for a cycle of increasing and decreasing pressures, and, in addition, at the maximum pressure, the effect of increasing the temperature-difference to 60 deg. C.—corresponding to a mean temperature of the specimen of 45 deg. C.—was determined. An indication was thus obtained of the effect of pressure and temperature on the thermal resistivity.

(c) Results of tests.

Before referring to the results, the factors which account for the thermal resistance of a composite material of the type under experiment will be considered.

The greater part of the thickness of the pile of stampings (about 90 per cent) is accounted for by the sheet metal. This portion has so low a resistance that, in spite of its great thickness, it contributes very little to the thermal resistance of the aggregate. By far the greater portion of the resistance is due to the high resistivity of the material composing the insulation and to the discontinuities between the superposed surfaces of the pile.

As the thermal resistivity K of the steel from which the punchings are made is of the order of 3, and the tests showed that the thermal resistivity K of a pile of fifteen insulated stampings was of the order of 120, the resistance of the steel only accounts for from 2 per cent to 3 per cent of the total. It is thus seen that as far as the resistivity of the aggregate, transverse to laminations, is concerned, the resistivity of the metal composing the sheets is practically immaterial. On the other hand, the thickness of the sheet metal, composing some 90 per cent of the aggregate, affects the numerical values of the transmission of heat when expressed in units of "resistivity," since this refers to a unit thickness of the material. Now the thickness of the metal sheet with which the present investigation is concerned has varied from specimen to specimen, so that it is clear that a better comparison of the relative resistances of the several coatings on the stampings would be obtained by using a unit which expresses the heat-conducting power irrespective of the arbitrary thickness of the metal. It would be preferable to express such power in terms of the thickness of the insulating coating. This thickness is, however, so small as to be difficult to measure accurately, and, moreover, it is affected to an uncertain extent by rust and other surface irregularities, and by burred edges of the specimens. Hence, in the following the "thermal resistance per stamping" has been considered.

In addition to expressing the results in terms of the "thermal resistance per stamping" the thermal resistivity K has also been calculated, the latter, of course, referring to a pile of stampings 1 cm in thickness. (See Tables 23 and 24.)

The measurement of thickness made on the stampings is recorded in Table 25.

The "total" thickness per stamping was obtained from measurement of the thickness of the pile of 15 stampings when under the maximum load. To get the

In Figs. 24 and 25 the "thermal resistance per stamping" has been plotted for the complete range of the tests.

Referring first to the effect of an increase of temperature on the transmission of heat, this was investigated, as has already been explained, by increasing the mean temperature of the specimen from 25° C. to 45° C. when under the maximum load. It will be observed from Fig. 24 that the result in the case of specimens Nos. 1 and 2 has been a pronounced decrease in the resistance per stamping amounting to some 30 per cent. The curves further show that the decrease is permanent since it was not appreciably affected by again lowering the mean temperature to 25° C., as was done in the subsequent observations. The phenomenon suggests that possibly the insulating media, which were " core plate japan " and "core plate varnish " respectively, softened under the combined effect of pressure and heat. In the case of the last-mentioned coating the stampings were found to have adhered slightly at the end of the experiments. The other specimens, Nos. 3 to 7, appeared to show also a small permanent decrease in resistance per stamping on raising the mean temperature to 45° C., but the decrease never exceeded 5 per cent in these cases.

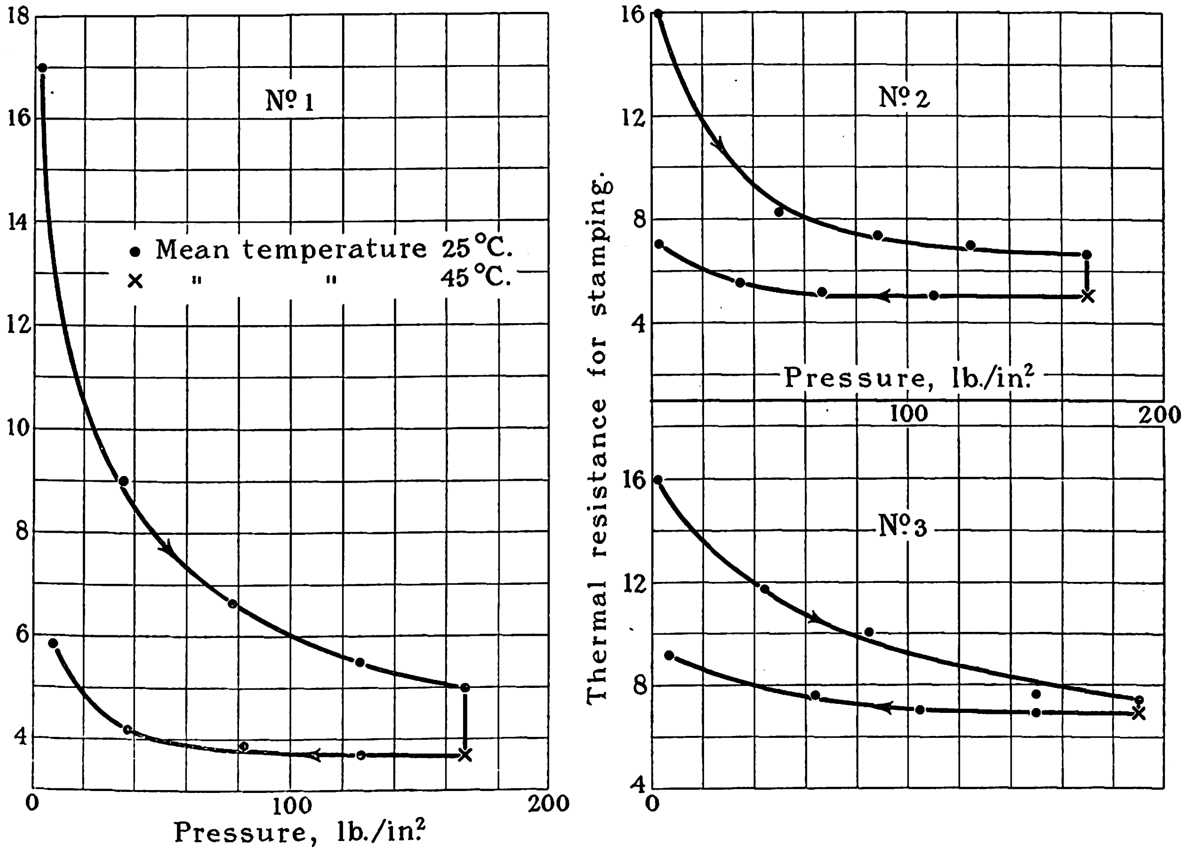

FIG. 24.—Curves showing the variation of the thermal resistivity of sheet-steel stampings under pressure.

As already stated, the effect of pressure was studied by taking each specimen through a complete cycle of increasing and decreasing pressures. Except in the case of No. 5, where irregular values were obtained, the curves for increasing pressure indicate a tendency to a minimum value for the thermal resistance. On decreasing the pressure the curves obtained for the several specimens departed considerably in shape from those for increasing pressure. If allowance is made for the permanent change due to heating when at the maximum pressure, the curve for decreasing pressure would give considerably the lower value for the resistance per stamping at any particular pressure. The scope of the investigation did not extend to a study of the effect of again increasing the pressures after the first cycle of increasing and decreasing pressures. A single experiment was, however, made with specimen No. 2 and the value, found for a final increase of pressure after completing the cycle referred to, fell on the curve previously obtained for decreasing pressure.

The fact that the relation between thermal resistance and pressure should depend on the maximum pressure to which the pile of stampings had been subjected is probably to be expected in aggregates of laminated materials.

As for the comparative values of the thermal resistance of the several stampings, the figures given in Table 23 refer to a pressure of 160 lb. per square inch, as taken from the curves for increasing pressures and for a mean temperature of 25° C. The pressure chosen for obtaining the comparative values was the highest pressure to which all the specimens were subjected.

The detailed results of the tests made are recorded in Table 24.

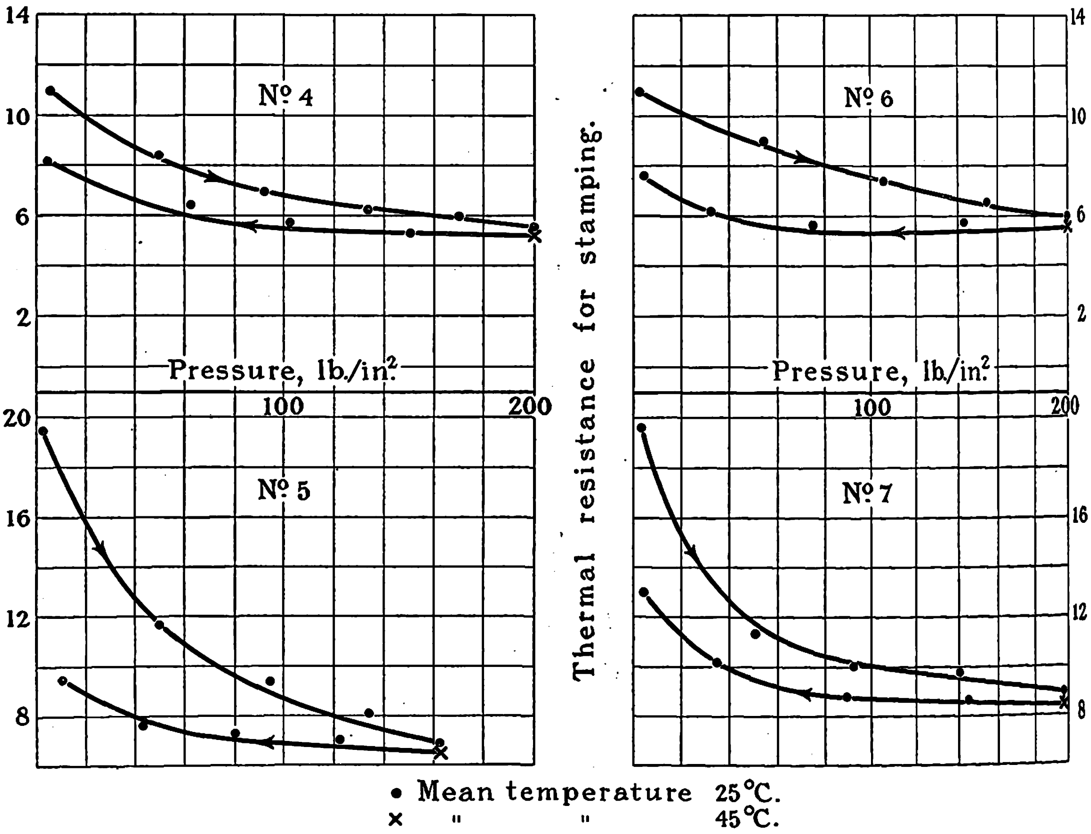

Fig. 25.—Curves showing the variation of the thermal resistivity of sheet-steel stampings under pressure.

It will be observed that a considerable range of values is found for the thermal resistivity at a pressure of 160 lb. per sq. in., that for core plate japan being the lowest. The figures apply to a mean temperature of 25° C. For a higher mean temperature, say 45° C., the values for both core plate japan and varnish would apparently be considerably lower than for the remaining specimens, owing to the large change shown by the two first mentioned under the combined effects of temperature and pressure, to which reference has already been made. As to the resistivities of the insulating coatings, if these are taken to be about one-tenth of the total thickness, the values will range from about 1 200 to 800. It may be remarked that these figures are slightly below the range of values found for the resistivity of paper by other observers.

It is of interest to compare the values obtained in the present investigation with that of Ott.* The latter investigator used two specimens of stampings, consisting of sheet iron 0·5 mm thick and paper 0·05 mm thick, the surface of the metal in one case being stated to be smooth and in the other granular. The resistivities found in these two cases, for a pressure of 50 lb. per square inch (3·4 kg per cm²), were 97 and 186, which values are within the range of those found in the present investigation.

---

* See Bibliography.

(*d*) *Summary of results.*

The transmission of heat through sheet-steel stampings has been investigated for specimens coated with the following insulating media, viz. core plate japan and varnish, insuline and paper (several specimens). The main results obtained are summarized below:—

(i) In all cases the sheet metal accounted for only a very small fraction of the total thermal resistance transverse to the laminations.

(ii) The thermal resistance K per stamping ranges from 8 to 16, i.e. 160–320 for a 0·02-in. stamping piled to 1 cm.

(iii) The specimens coated with japan and varnish showed permanent decrease of resistance of the order of 30 per cent on raising the mean temperature from 25° C. to 45° C. when under the maximum pressure, and under these conditions the transmissions of the two specimens named were considerably higher than those of the remaining specimens, which gave only small changes when subjected to the combined effect of heat and pressure.

(iv) Experiments with a cycle of pressure, first increasing and then decreasing, showed that the latter part of the cycle gave the higher values for the heat transmission at any particular pressure.

Part IV.

A Study of the Thermal Resistivity of Air Spaces: Results of Tests Carried out by the Research Laboratories of the Metropolitan-Vickers Electrical Co., Ltd., and Kindly Placed at the Disposal of the Association by Mr. A. P. M. Fleming, C.B.E.

(*a*) *General.*

In considering the paths of heat flow in electrical machinery and apparatus, it is necessary to make an allowance for the presence of air spaces, intended or otherwise. In many cases air spaces are located in such a way that appreciable air flow cannot take place through them, so that heat has to be transmitted through a layer of still air. Examples of unintended air spaces are those due to the imperfect fit of a field coil on a pole or a stator conductor wrapping in a slot. In such cases, only the possible magnitude of the thermal resistance due to the air spaces can be estimated and not the actual magnitude, since all that is known is that the air spaces are not likely to exceed a certain value in thickness. However, taking the maximum thickness that is likely to occur, one can calculate the thermal resistance and see whether it is important compared with the total resistance of the heat path under consideration. The uncertainty in the total resistance due to the presence or absence of the air space can then be estimated and sufficient margin allowed for keeping the temperature-drop within the required limits.

Many cases occur where the thickness of an air space is definitely known. In such cases the thermal resistance can be estimated with fair accuracy if suitable data are available. The tests described in this report were carried out with the object of providing such data. The accuracy claimed for these results is not high, and probably does not exceed 5 per cent, but it is quite sufficient for engineering purposes. By various refinements in the method and apparatus, a considerably higher degree of accuracy could be attained. This would be appropriate to an exhaustive investigation of the subject, but in view of the fact that the subject is not of primary importance to designers, the expense of an exhaustive investigation can hardly be justified.

The tests herein referred to were carried out with a thermal resistivity apparatus which had been developed for measuring the resistivity of refractories and electrical insulating materials.

(*b*) *General arrangement of the apparatus.*

The general set-up of the apparatus is shown diagrammatically in Fig. 26. Two specimens A and B of the same dimensions are used. Between the two specimens is placed a square central electrode C surrounded by a guard ring electrode D, the guard ring being separated from the central electrode by a small air space. Both these electrodes contain heaters made up of nichrome ribbon wound on flat asbestos slate formers. On the other sides of the two specimens are placed the heavy electrodes E and F which also contain heaters.

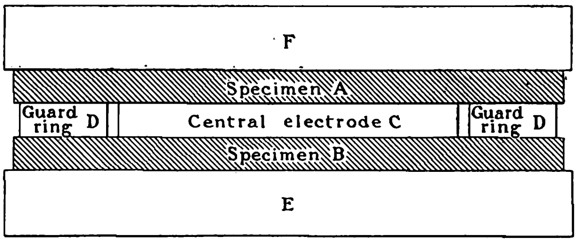

Fig. 26.—Diagram of apparatus used for the study of the thermal resistivity of air spaces.

By adjusting the currents in the various heaters the temperatures of the guard ring and central electrodes are made equal, whilst the temperatures of the electrodes E and F can be adjusted to give any desired temperature-drop across the specimens. When steady temperature conditions are obtained the input to the central heater gives a measure of the quantity of heat being transmitted across the specimens, and from a knowledge of the steady temperatures and the dimensions of the electrodes and specimens the thermal resistivity of the specimen can be deduced. Temperatures are measured by means of platinum-rhodium thermo-couples suitably placed.

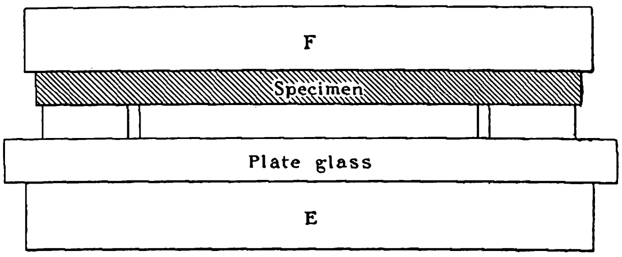

Fig. 27.—Alternative arrangement of apparatus shown in Fig. 26.

In certain tests where it may be desirable to obtain measurements on only one specimen, an alternative arrangement of the electrodes can be used, as shown in Fig. 27. Here the bottom specimen is replaced by a high-resistance material such as a sheet of plate glass, and the temperatures of the central guard ring and bottom electrode E are all adjusted to the same value. Under steady temperature conditions the input to the central heater is now all dissipated through the one specimen to the top electrode F.

(*c*) *Considerations of design.*

In designing the electrodes many points required special attention. The more important of these are outlined below.

The electrodes required to be made of sufficiently massive dimensions to ensure temperature equalization over the whole surface. For this purpose it would have been best to make them of copper, but a preliminary trial showed that copper scaled very badly at a temperature of 500° C. when in the presence of asbestos insulation. Brass was found to behave much more satisfactorily, and was therefore used.

The thermal resistance of the air path between central and guard ring electrodes was required to be as large as possible to prevent a slight want of balance in temperature between the two electrodes causing an appreciable flow of heat from the one to the other. For this reason the air gap was made $\frac{1}{8}$ in. wide, and the thickness of the electrodes kept down to a minimum.

The same apparatus was required to cover measurements in thermal resistivity K, expressed in the number of degrees C. drop in temperature per cm of material to cause a heat flow of 1 watt per cm^2, from 50 to 4 000. Moreover, the temperature-drop across the specimen was required to be kept low owing to the known large variation in resistivity with temperature of most materials. It was necessary, therefore, to make the electrodes of such a size that the watt input even for very high values of K would be easily measurable and not appreciably affected by other experimental errors, but at the same time without increasing the thermal capacity of the electrodes to such an extent as to make the time-constant of the apparatus large, and thus making the time required to obtain steady conditions in any test unreasonably long.

Leads to the central electrode heater had to be arranged so that conduction effects along them would be negligible compared with the total input. This was chiefly obviated by the fact that these leads had to pass through the guard ring, which is at the same temperature as the central electrode during a test. The whole of the heaters and leads had to be made suitable for withstanding prolonged temperatures of well over 500° C. Mica was used to insulate the heaters from the electrodes, and porcelain tubes to insulate the lead-in wires. The final arrangement and design of the electrodes is shown in detail in Figs. 28 to 31 inclusive.

With regard to temperature measurement, thermocouples were, of course, used. It was considered advisable for temperatures as high as 500° C. to use couples of platinum and platinum-rhodium.

Accordingly, couples were made up from wire of about 0·01 in. diameter supplied by Messrs. Johnson, Matthey and Co., of Hatton Garden, London. For the measurement of temperature balance between the central electrode and guard ring, one couple was placed on each of these electrodes. The two wires of the couple were secured separately on to the metal of the electrode by means of grub screws, as shown in Figs. 29 and 30, the couple wires being insulated from the electrode by thin silica tubing. Provision was also made on the outer electrodes for temperature measurement by similar couples also secured by grub screws near the surface of the electrode. The thermal e.m.f.'s set up in the couples were measured on a Tinsley thermo-couple type potentiometer, capable of reading to one microvolt. Thus any contact resistances between the couple wires and the electrode were made of no account.

The temperature-drop across the specimen was, in certain cases, taken as the temperature-difference between the central and outer electrodes. In other cases, thermo-couples were buried in the specimens at known depths.

(*d*) *Considerations of accuracy.*

(i) *Temperature measurement.*

A calibration of thermal e.m.f. against temperature-rise was supplied with the thermo-couple wire by the makers. As a check on this, however, one of the couples was calibrated at the National Physical Laboratory. Very good agreement existed between the two calibrations, and the actual temperature measurements at 500° C. were correct to ± 1 deg. C., whilst the balance of temperature between guard ring and central heater could be obtained to less than $\frac{1}{4}$ deg. C. Assuming balance to be obtained to this accuracy, and taking K for the air space between the guard ring and central heater as 1 000, this lack of balance would cause a flow of heat from the one electrode to the other of 0·07 watt, on a minimum input of about 5 watts. Conditions are usually much better than this, so it can be said that the error due to lack of temperature balance between guard ring and central electrodes is always less than 1 per cent.

(ii) *Measurement of thickness.*

These measurements were usually correct to 2 per cent. In the tests on resistivity of air spaces the electrodes were spaced by very small spacers of silica or sheet glass, the thickness of which was measured by micrometer. The thickness of the gap was also checked by means of feelers, an accuracy of 1 per cent being obtained except for the very small gaps.

(iii) *Measurement of power input.*

This was measured by ammeter and voltmeter to an accuracy of $\frac{1}{2}$ per cent.

(iv) *Overall accuracy.*

Reviewing the possible causes of error as outlined above in the tests on air spaces the overall accuracy is thought to be of the order of ± 5 per cent.

(*e*) *Method of testing.*

The thermal resistivity of a gas can be directly determined from a knowledge of the viscosity and specific

heat at constant volume of the gas, but in practice this theoretical value is of little use, owing to the fact that transmission of heat even through thin films of gas takes place not only by conduction, but by convection, and possibly radiation also.

The apparatus was set up as shown in Fig. 27 with a sheet of ½-in. plate glass interposed between the bottom electrode and the central and guard ring electrodes. Before commencing the tests the surfaces of all the electrodes were re-machined flat and smooth, and the guard ring and central heater machined to the same thickness. The air space between guard ring and central heater was filled with Kieselguhr Diatomite powder to prevent the formation of air eddy currents, while still preserving a high thermal resistance between the two. The top electrode was packed off the guard ring by small spacers of glass or silica to give the required air-space between the central and top electrodes.

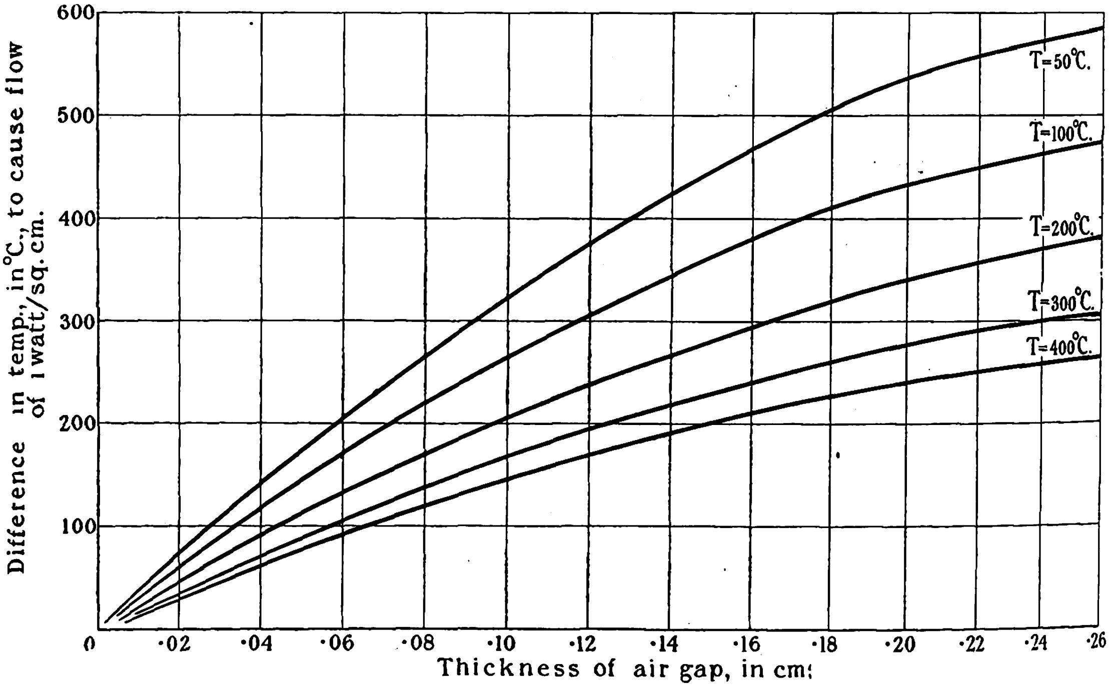

FIG. 32.—Thermal resistivity of air gaps at various temperatures and spacings, excluding effect of black radiation.

Tests were then made of the resistivity of the air space for various mean temperatures of the air space up to 400° C., the temperature-drop across the air space being taken as the temperature-difference of the central and top electrodes.

Curves were obtained of resistivity against mean temperature for gaps varying in width from 0·5 mm to 2·5 mm. These values of resistivity included the effects of:—

(i) Pure conduction across the air space.
(ii) Convection eddies set up in the air space.
(iii) Radiation loss across the air space.

It was not intended to separate the conduction and convection effects, but it was considered worth while to separate these losses from the radiation loss. To do this necessitated a knowledge of the emissivity coefficient of the surfaces of the electrodes as used in the tests. To obtain this coefficient, therefore, the following test was made:—

With the top electrode removed and the central electrode surface untouched, a curve of heat dissipation from this latter surface in watts per cm² against temperature-rise of the surface was obtained. This surface was then painted dull black, and a similar curve again obtained. The radiation loss in this latter case was then calculated from the radiation law:—

$$\text{Watts per cm}^2 = 5\cdot72 \times 10^{-12}(T_1^4 - T_2^4)$$

where T_1 and T_2 are the absolute temperatures of the surfaces and surroundings respectively. In this way the radiation was separated from the convection. (The effect of the thermal resistance of the coating of paint was considered and found to be negligible.)

Returning now to the first curve, the losses were split up into convection and radiation. Hence the value of the emissivity coefficient for the surface was obtained from the ratio of the radiation loss in the two cases. It was found to be 0·476.

The radiation across the air space in watts per cm² per deg. C. difference of temperature of the electrodes at mean temperatures of 50° C., 100° C., 200° C., 300° C., and 400° C. was then calculated, being $(0\cdot476)^2 \times$ the full or black radiation for the same conditions—calculated from the formula above. It was thus possible to convert the original test curves of resistivity against air-gap width into a set of curves showing the required difference in temperature in degrees C. to cause a flow of 1 watt per cm² across varying widths of air gap at different mean temperatures, when radiation is entirely absent. These curves are plotted in Fig. 32. Again, a similar set of curves was easily calculated on the assumption of black radiation across the air space in addition to conduction and convection, and these curves are given in Fig. 33.

(*f*) *Discussion of results.*

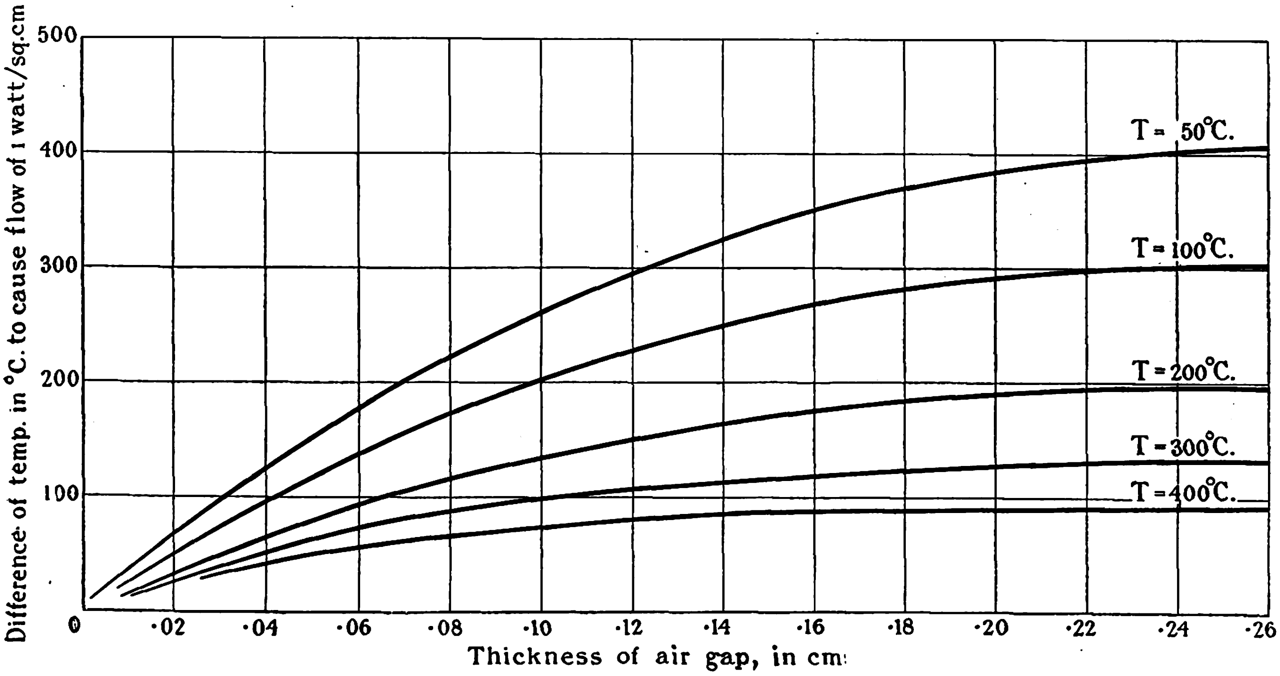

FIG. 33.—Thermal resistivity of air-gaps at various temperatures and spacings, including effect of black radiation.

Referring to Fig. 32 (no radiation) it will be seen that for a given mean temperature the thermal resistance does not increase in proportion to the thickness of the air space. The reason is that with very small thicknesses heat transmission takes place by conduction only, but as the thickness is increased the air has greater freedom of motion, and convection becomes of increasing importance, supplementing the transmission by conduction. It will be seen that the resistance for a given thickness varies considerably with mean temperature.

With regard to radiation, the surfaces generally occurring in electrical machinery and apparatus all have high radiation coefficients. Thus, dull painted surfaces of almost any colour and varnished surfaces have radiation coefficients very nearly equal to unity, while dull or rusty iron surfaces may be over 0·75. For practical purposes the curves which include the effect of full radiation should therefore be used.

The results given in this report may be checked with other published data as follows:—

Professor Miles Walker in his book "Specification and Design of Dynamo Electric Machinery," page 223, gives a curve from which the thermal resistance of air spaces of different thicknesses may be obtained. The mean temperature at which the measurements were made is not stated. A comparison of results is given below, the Metropolitan-Vickers' results including the effect of full radiation.

Thermal Resistance, deg. C. for 1 *watt per cm*^{2}.

	Walker	M.V.Co.
Mean temperature	Not stated	50° C.
Resistance for 0·1 cm ..	220	260
Resistance for 0·2 cm ..	350	382

A more accurate check may be obtained as follows:—

If the curves excluding radiation be taken and the slope for small thicknesses found, the thermal resistivity of air can be calculated. The values in watts and centimetres for different mean temperatures are given below:—

Mean temperature, ° C.	Thermal resistivity K
50	3 800
100	3 100
200	2 300
300	1 820
400	1 580

Now if the conductivities be plotted against mean temperature the points will be found to lie on a straight line, with the exception of the 400 degree point, which is probably in error. Ignoring this point and producing the line to zero mean temperature we obtain a conductivity of $2 \cdot 09 \times 10^{-4}$ at 0° C. The conductivity of air at 0° C. and in C.G.S. units is given on page 52 of Kaye and Laby's "Constants" as $5 \cdot 22 \times 10^{-5}$. Converting this into the units employed above by multiplying by

4·184 gives the value $2\cdot18 \times 10^{-4}$, thus showing an agreement to within about 4 per cent.

ACKNOWLEDGMENTS.

For the main series of tests the E.R.A. is indebted to Dr. G. W. C. Kaye, Dr. Ezer Griffiths, F.R.S., and Mr. F. H. Schofield, B.Sc., of the National Physical Laboratory.

For assistance in preparing the test specimens the Association is indebted to Mr. B. G. Churcher (Metropolitan-Vickers Electrical Co., Ltd.), Mr. A. D. Sloan (English Electric Co., Ltd.), and Mr. H. Warren (British Thomson-Houston Co., Ltd.).

For the investigation on the thermal resistivity of air spaces, and for many valuable suggestions during the progress of the researches, the Association wishes to acknowledge its indebtedness to Mr. B. G. Churcher.

APPENDIX I.

ESTIMATION OF THE THERMAL CONDUCTIVITY OF THE INSULATION ON A RECTANGULAR BAR.

The peculiar shape of the cross-section of insulating material wound on a rectangular bar is such that its thermal conductivity does not admit of exact mathematical treatment.

Two cases are illustrated. Fig. 34 shows the cross-section of an insulated bar; the heat flows straight through the flat sides, but the stream lines are disturbed at the corners. The disturbance does not extend far from the corner, and may be examined by investigating one half of one corner, as between the lines A and B in Fig. 34.

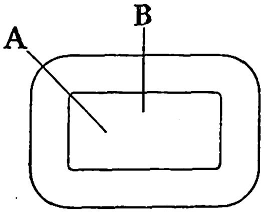

FIG. 34.—Section of bar, showing part A B.

Two cases are so examined in Figs. 35 and 36, in which isothermals are shown surrounding the bar and heat flow radiating from it.

These diagrams are got by trial and error on the principle that only one set of curves is possible, satisfying the following conditions:—

(i) The lines of heat flow must everywhere be at right angles to the isothermals.

(ii) The figures formed by intersection must (if taken small enough) be rectangles having the same ratio of length to breadth. (They may conveniently be made squares.)

The assumption is made of homogeneous conductivity, and that the inner and outer surfaces of the insulation are isothermals.

The conductivity of unit cube is taken as unit conductivity giving unit heat-flow for unit temperature-difference. Taking unit length of the bar, we get—

$$\text{Conductivity} = \frac{p + at}{t}$$

where p = peripheral length, t = thickness, and a = a correction factor for corner effect.

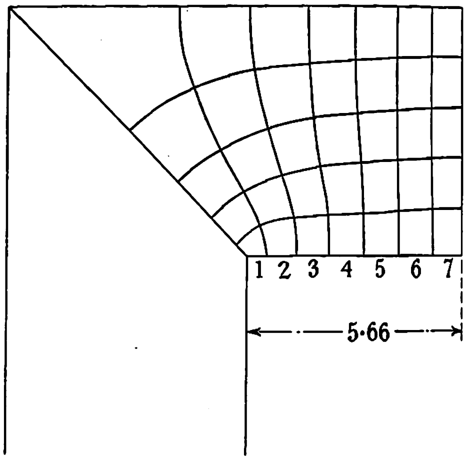

FIG. 35.—Graphical diagram of isothermals and lines of heat flow for square corners.

Case 1 (*Fig.* 35).

Let all corners be square. Taking the unit as 1 cm (the diagram shows $\frac{1}{2}$-cm squares), then $t = 5$. Assume temperature-difference as shown = 5, i.e. 1° per unit of t. Now where the peripheral length in the whole of the disturbed area ending at a corner is 5·66 cm, the figure shows that the corner effect allows 7 units of heat to flow; that is an excess of 1·34 on one side of one corner, or an excess of $1\cdot34 \times 8 = 10\cdot72$, taken on the two sides of the four corners. This is equivalent to an addition of 10·72 cm to the periphery for a thickness

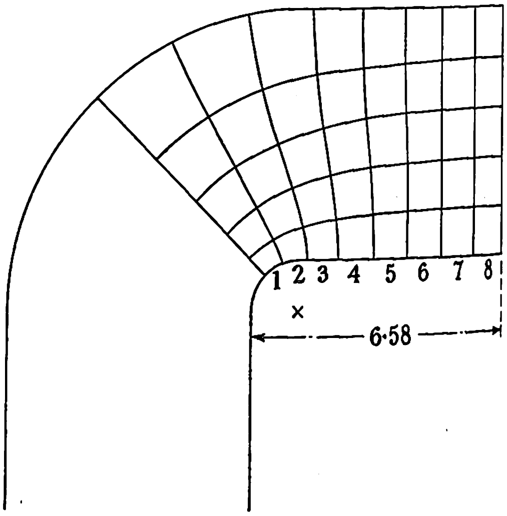

FIG. 36.—Graphical diagram of isothermals and lines of heat flow for rounded corners.

of 5 cm, and is proportional to the thickness; hence the correction factor is $10\cdot72/5 = 2\cdot14$, or:—

$$\text{Conductivity} = \frac{p}{t} + 2\cdot14$$

Case 2 (*Fig.* 36).

Let the corners be rounded to a radius $= t/5$, and let the thickness of the insulation be uniform all over.

Now where the peripheral length in the whole of the disturbed area ending at a corner is 6·58, measured flush with the square end, the figure shows that the corner effect allows 8 units to flow; this is an excess of 1·42 on one side of the corner, or 11·36 on the four corners, hence the correction factor = 2·27, or:—

$$\text{Conductivity} = \frac{p}{t} + 2\cdot27$$

General.

Comparing Cases 1 and 2, it will be seen that the loss of periphery due to rounding-off the inside corner has been more than compensated for by the rounding-off of the outside corner. A radius on the corner $= t/5$ is more than is generally employed; hence the correction factor is of the order of 2·2 on an average.

On scaling the q squares it is thought that the cumulative error is probably not more than about $\frac{1}{2}$ mm, which taken on a difference of 1·34 to 1·42 corresponds to ± 0·08 on 2·14 to 2·27.

On a bar of any length l, substituting A the surface area for the peripheral length, and taking the conductivity as k for 1 cm cube, we get for Case 1:—

$$\text{Conductivity} = k\left(\frac{A}{t} + (2\cdot14 \pm 0\cdot08)l\right)$$

For Case 2, if the bar measures $b \times c$ centimetres in cross-section, we have:—

$$\text{Conductivity} = k\left(\frac{2(b+c)}{t} + (2\cdot27 \pm 0\cdot08)l\right)$$

and for all present purposes we may take:—

$$\text{Conductivity} = k\left(\frac{2(b+c)}{t} + 2\cdot2l\right)$$

NOTE.—Since writing the above our attention has been drawn to a mathematical treatment of this subject published in Jeans's "Electricity and Magnetism," 4th ed., pp. 277–9. This reference gives 2·23 as the added length in terms of the thickness when the sides of the coil are appreciably long compared with its thickness.

The method employed in Appendix I has, however, been reproduced as it gives a general solution applicable where there is no rigid mathematical solution.

PHENOMENA CONNECTED WITH THE COLLECTION OF CURRENT FROM COMMUTATORS AND SLIP-RINGS.*

By H. G. Taylor, M.Sc. (Eng.), Graduate.

(*Paper first received* 21*st January, and in final form* 18*th March*, 1930.)

Summary.

One of the troubles experienced in the collection of current is that of "copper picking." A description is given of an experimental investigation of this phenomenon, and this is followed by a critical survey of existing data, leading to an explanation to account for this deposition of metal, and an investigation into the mechanism of the passage of current from the slip-ring or commutator to the brush.

The variation of contact voltage-drop with speed, brush pressure and current is shown. Peripheral speeds higher than previously have been used and an investigation has been made at very low current densities.

In order to show the variation of contact voltage-drop, oscillograms have been taken which show its fluctuating nature. These oscillograms show the effect of increased speed and brush pressure, and the change in nature of the contact as the latter is reduced. Intermittent contact is shown to account for rising voltage-drop with speed, but a speed is attained at which an air film is drawn between the brush and the ring.

Introduction.

The author was led to make this investigation largely as a result of a paper presented to the Institution in 1919 on "Carbon Brushes." † This paper revealed a great diversity of opinion, and showed that considerable information was still required on fundamental questions of current collection, and it was in an attempt to elucidate these points and to extend the range of knowledge that this work was undertaken.

The problem of voltage-drop between contacts having relative motion has engaged the attention of a number of experimenters, but it is believed that this is the first time that results showing the variation of contact-drop at speeds greater than 10 000 ft. per minute have been published. The inherent difficulties of an investigation of this nature have been frequently expressed. The chief difficulty is that of reproducing conditions. The contact-drop is to a considerable extent dependent on the state of the surface of the ring and whilst rotation takes place this is continually changing due to oxidation, abrasion and the deposition of moisture and dirt. It is therefore practically impossible to obtain the same contact-drop on any one day as was obtained on the previous day with the same conditions of speed, current and brush pressure.

Recommendations for the ideal test apparatus for determining voltage losses due to contact were made by H. R. Edgecomb and W. A. Dick in a paper presented to the American I.E.E. in 1913,* and as far as possible these have been followed in the construction of the apparatus used by the author.

The problem of copper picking has always been a source of trouble to the engineer, and the phenomenon has never been satisfactorily explained. Because of this, a considerable portion of the paper is devoted to a critical review of existing opinions on the subject and to an analysis of the results of an experimental investigation of the phenomenon.

The Apparatus.

The apparatus used for the above tests consisted essentially of a pair of phosphor-bronze slip-rings $12\frac{5}{8}$ in. dia. and each $\frac{5}{8}$ in. wide mounted on a shaft and direct-coupled to a 6 000-r.p.m. motor. The brush gear was mounted quite separate from the bedplate, so as to eliminate transmitted vibration, and the brushes used were the Morgan Crucible Co.'s type HM.6. The brushes were $\frac{1}{2}$ in. × $\frac{7}{8}$ in. × $1\frac{1}{2}$ in. and they rested side by side on a hard-wood support. The $\frac{1}{2}$ in. × $\frac{7}{8}$ in.-face was in contact with the ring—the longer dimension being vertical. The brushes were maintained in contact with the rings by pivoted arms. At the top of each arm the desired force was applied by a string, to the other end of which was attached a weight.

Copper Picking.

The surface of the rings was prepared by grinding and by the use of glass paper and very fine emery paper. After the first run it was found that on one brush small flakes of phosphor bronze were deposited. These pieces of metal were removed and on reversing the current the phenomenon was found to occur on the other brush—in each case at the brush where the current flowed away from the rings (henceforth referred to as the negative brush). This phenomenon is similar to that which occasionally occurs with copper commutators and is referred to as "copper picking." It appears that with a commutator these flakes may be formed in very large numbers, and, in addition to those which adhere to the brushes, many may alight on the surrounding bedplate. The general opinion seems to be that these flakes leave the commutator in their fully formed state, and some unfortunately adhere to the brushes and thereby cause a great reduction in contact-drop and scoring of the commutator. The author's opinion is, however, that every flake is formed on the brush by the aggregation of small particles, and is then swept off the brush face, and a fresh one formed. This certainly has been the case with phosphor-bronze slip-rings. The many flakes which alighted on the surrounding parts were identical in form with those picked from the brush face. The chips or flakes were discoloured purple and blue with oxide, and this, together with the small curled projections visible under the microscope (see Fig. 13), serves to indicate that intense heating takes place in their formation. The flakes are long and narrow and appear to grow mainly in the direction of motion of the ring. Several may fuse together at one end and give a resultant flake of forked appearance (see Fig. 14).

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† P. Hunter-Brown: "Carbon Brushes: considered in relation to the Design and Operation of Electrical Machinery," *Journal I.E.E.*, 1919, vol. 57, p. 193.

* See Bibliography, (37).

It is generally understood that copper picking may be reduced or cured by improving the mechanical conditions and reducing vibration. Everything possible along these lines was done, but without complete success. The rings were tested for concentricity with a dial indicator reading to 0·001 in., but not the slightest movement of the needle was apparent.

In general, copper picking was restricted to the negative brush, but on several occasions it took place also on the positive, and on one occasion it took place on both brushes at once with no current flowing. This occurred after the machine had been "running-in" the brushes at 4 000 ft. per minute for 3 hours. The flakes in this case were about 0·6 in. long by 0·1 in. wide. Several methods of preparing the surfaces of the rings were tried and the best result was obtained from burnishing with a chain burnisher. It is possible to obtain a deposit of metal on the carbon when there is no relative motion, but this only takes place with a current of the order of 200 to 300 amperes per square inch. In this case the deposit appears to be copper and not phosphor bronze, and is in the form of very many minute specks—entirely different from the deposit when running.

It has been suggested [*] that copper picking may be due to any of the following three causes.

(1) Mechanical breaking-up of the copper crystals during the process of drawing the bar through the die, or a change in structure due to alternate heating and cooling in service.

(2) Electrolytic copper contains a certain amount of hydrogen. The presence of hydrogen may affect the structure of the metal or its behaviour when current is passed from it to the carbon.

(3) Electrolytic copper sometimes contains small traces of sodium and this may possibly affect the structure or the electrical wear.

None of these theories will hold for the particular case under consideration. The fact that the phenomenon occurs with phosphor bronze as well as with electrolytic copper and with castings as well as with drawn copper, and that the deposits were actually phosphor bronze and not an electrolytic separation of any one metal, certainly controverts these theories.

The various descriptions of copper picking show that the phenomenon with a commutator is rather different from that occurring with slip-rings. With a commutator more flakes are produced, they are smaller, and they do not adhere so firmly to the brush. This difference is accounted for by the essential difference between the surfaces of the commutator and slip-ring. The smooth surface of the slip-ring has much less tendency to remove the flakes from the brush face than has the surface of the commutator with its alternate copper bars and mica. There being less tendency to remove the flakes they become larger, adhere more firmly to the brush, and are produced in fewer numbers.

However smooth the surface of the brush and ring may be, contact is actually only possible at three points, and with the ring in motion these points are rapidly changing in position. Experimental justification is given for this by Stine,[*] and Baily and Cleghorne.[†] Stine's paper gives a curve connecting contact-drop with the current per brush. The one curve was obtained by plotting values obtained by using three different sizes of brush, thus indicating that, as regards contact-drop for one particular current, the size of the brush had no effect. The same total pressure was used in each case and the result can only be explained by assuming that the actual area of intimate contact between the brush and the ring is the same for each brush. A set of curves is also shown connecting contact-drop with total brush pressure at fixed nominal current densities for three sizes of brush. Three separate, similar, curves are obtained one above the other, the greatest voltage-drop taking place with the largest brush, and the least voltage-drop taking place with the smallest. This is due to the fact that the actual area of contact is the same in each case. The nominal current density being the same for each type of brush, the largest brush carries the greatest current and therefore, owing to the actual contact area being no greater than that with the smallest brush, the actual current density and consequently the voltage-drop are highest. Hence the contact-drop increases with the size of the brush for a fixed nominal current density and constant total brush pressure.

Further justification for the three-point contact theory may be deduced from the work of Baily and Cleghorne. From their experiments they obtain a formula for voltage-drop in terms of current and brush pressure. It is for a particular type of brush and its application is necessarily limited to the range over which the experiments were conducted. It is given as

$$E = \frac{i^{0\cdot28}}{1 + 0\cdot22\sqrt{P}}$$

where P = brush pressure in ounces per unit area, and i = current in amperes per unit area.

If now the area of the brush be reduced to $1/n$th of its value, the current density will be ni and the pressure intensity Pn, and the voltage-drop will be changed to

$$E_1 = E\frac{(in)^{0\cdot28}}{i^{0\cdot28}} \cdot \frac{1 + 0\cdot22\sqrt{P}}{1 + 0\cdot22\sqrt{Pn}}$$

Within large limits the ratio of E_1 to E differs very little from unity. For example, take $P = 2$ lb. per sq. in. and $n = 5$, i.e. compare two brushes one having five times the nominal contact area of the other; then

$$E_1 = E(5\cdot0)^{0\cdot28} \cdot \frac{1 + 0\cdot22\sqrt{32}}{1 + 0\cdot22\sqrt{5 \times 32}}$$

whence $E_1 = 0\cdot93E$.

---

[*] See Bibliography, (11), p. 299.

[*] See Bibliography, (16).

[†] *Ibid.*, (22).

Hence reducing the brush to 1/5th of its size has the effect of reducing the contact-drop only 7 per cent. It is thus clearly evident that the contact-drop is practically independent of the nominal area of the brush. If conduction were taking place simultaneously over the whole of the brush surface this would be inconceivable, hence we are forced to the conclusion that conduction takes place at small points of contact, the number and area of which bear no relation to the size of the brush.

In optical work it is difficult to grind two surfaces together so that the maximum distance between them nowhere exceeds $0 \cdot 5\mu$, but Rother has shown * that with a contact-drop of $1 \cdot 5$ volts a gap of only $0 \cdot 07\mu$ may be considered as an insulator between two metal surfaces, which further confirms the view that current conduction does not take place over the whole surface of the brush.

Assuming, then, the three-point contact theory to be true, three important facts follow:—

(1) Owing to rapid changing of points of contact very minute sparking must be taking place continuously.

(2) The current density at the points of contact must be very high.

(3) The pressure intensity at the points of contact must be very high.

Arising out of (1) and (2) we have the corollary that the points of contact must be instantaneously at a very high temperature. The result of this is that volatilization of the carbon takes place and the atmosphere around the point of contact is conducive to the maintenance of current flow through the medium of an arc. This has been fully confirmed by a recent paper by J. Neukirchen † which describes in some detail the mechanism of current transfer, and gives reasons for the variations of contact resistance which induce sparking.

It has been shown ‡ that the curves connecting brush contact resistance with current density closely resemble those connecting potential-drop and current in an arc of constant length, and experiments have been made which support the theory that elementary arcs are formed at and around the points of contact. With the formation of the arc, metal is carried from the ring and deposited on the carbon, just as metal is deposited from the (positive) metal electrode on to the work in the well-known metallic arc welding process.

This is the explanation of what is sometimes known as the "electrical wear" of a commutator or slip-ring. The process is taking place continuously, and it is a well-known fact that the wear under the negative brush (speaking in a motor sense) is much greater than that under the positive. Given suitable conditions, the speck of metal formed on the brush face adheres and forms the nucleus of a metal deposit of considerable size. High speeds encourage copper picking, and in accordance with the above explanation this is to be expected because (1) an increase of speed means that more work is done against friction at the points of contact, so increasing the maximum temperature, and (2) vibration increases with speed and more violent sparking takes place. The effect of increased brush pressure is also to raise the temperature and so make the conditions more suitable for copper picking. At high speeds the difficulties of current collection are considerable because a high brush pressure must be used to assist in maintaining intimate contact and so prevent copper picking, but at the same time this high brush pressure increases the temperature at the points of contact and so assists copper picking.

The deciding factor as to whether the deposit shall adhere to the brush face is probably the temperature of the point of contact, as deposition appears to be increased by all those factors which tend to raise the temperature. If the speck of metal sticks firmly to the brush, it will constitute a point of contact by virtue of its being at first higher than the remainder of the brush; scoring of the ring, accompanied by intense heating, then occurs, and metal is scraped off the ring and fuses to that already on the brush. The trouble becomes rapidly cumulative as, in addition to the heat produced by friction, the whole of the current will now be passing through the metal-to-metal surface, and a solid flake or scale of phosphor bronze is the result.

It should be noted that the position of the points of contact between the brush and the ring is normally rapidly changing, and it is this fact which distributes the heat uniformly over the brush face and so prevents pitting. When, however, a flake commences to form, this changing of position of the points of contact ceases to take place, with the result that intense local heating occurs. With regard to the case of deposition on the positive brush, and to the case where deposition occurred without the flow of current, it can only be suggested that the first particle of phosphor bronze became deposited on the brush by some abnormal means. It may have been released from some minute blow-holes on the surface of the rings; a microscopically thin and small flake formed by polishing may have been detached from the surface of the ring; or, finally, the ring may have been scored by a particle of abrasive matter in the brush. Once the first particle has been deposited and has adhered to the brush face the flake may, quite conceivably, be formed independently of the flow of current. In view of the considerable wear which takes place at negative slip-rings it appears that a very large amount of material which never adheres to the brush face is removed from the ring.

CONTACT-DROP.

The variation of contact-drop with peripheral speed, current density and brush pressure has been previously investigated by a number of experimenters and the opinion has not infrequently been expressed that it is difficult to reproduce values of contact-drop. The drop may vary with (1) composition and physical characteristics of brush; (2) composition of rotating part; (3) fit of brush in holder; (4) brush pressure; (5) peripheral speed of rotating part; (6) temperature; (7) humidity; (8) current density; and (9) condition of surface of rotating part. In this work (1), (2), (3) and (7) have been maintained constant. The variation with temperature was found to be small, but nevertheless the temperature was kept practically constant over each particular test. Of the remaining items, viz. (4), (5),

---

* See Bibliography, (31).

† *Ibid.*, (35).

‡ *Ibid.*, (24).

(8) and (9), (9) was beyond control but its effect was only considerable when running under severe conditions, i.e. at very high speeds; of (4), (5) and (8), two always were retained constant whilst the third was varied.

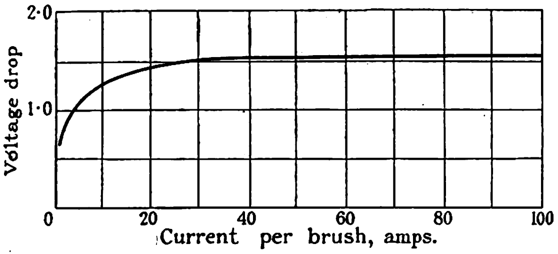

FIG. 1.—Voltage-drop and current. Brush pressure = 2 lb. per sq. in.; speed = 6 560 ft. per minute; positive brush.

The variation of contact-drop with current is well known for normal values of current, and a typical curve is shown in Fig. 1. In view of previous statements when referring to copper picking it will be apparent why the curves are plotted on a basis of current per brush and not per square inch, although on account of the custom of referring to the latter it may be stated that the area of the brush used throughout the experiments was 7/16 sq. in.

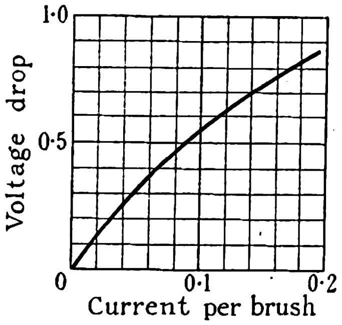

FIG. 2.—Negative brush, ring stationary. Brush pressure = 1½ lb. per sq. in.

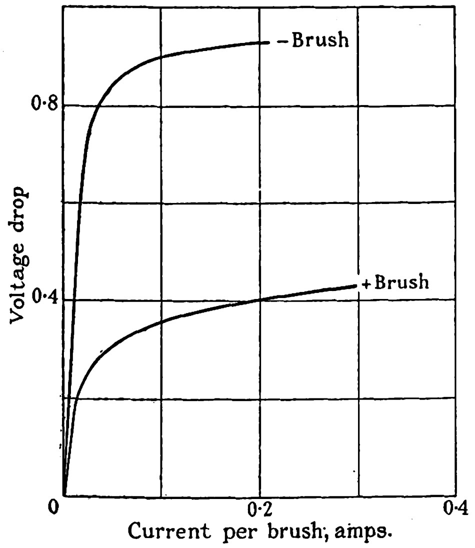

FIG. 3.—Variation of voltage-drop with small values of current.

Speed = 8 000 ft. per minute; brush pressure = 2 lb. per sq. in.

The author has been unable to discover that the variation of contact-drop with very low values of current has ever been thoroughly investigated, and diversity of opinion was shown in the discussion of a paper on “ Carbon Brushes in Relation to Electrical Machinery.” *

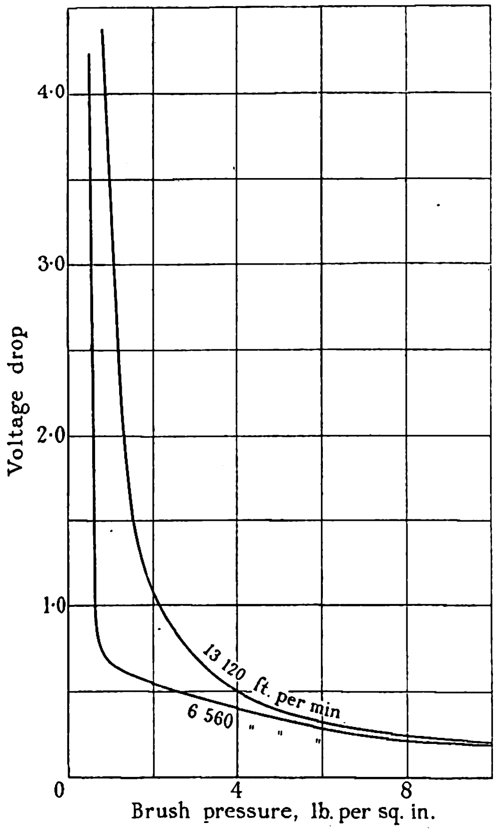

FIG. 4.—Brush pressure and voltage-drop. Current = 20 amperes per brush; negative brush.

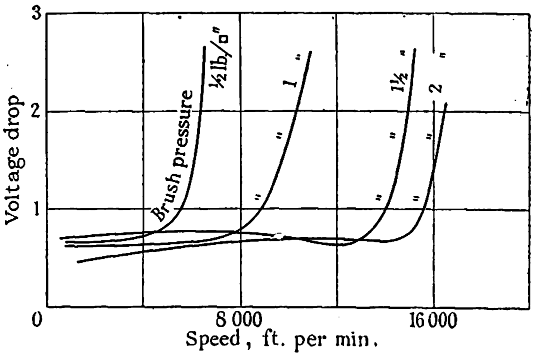

FIG. 5.—Voltage-drop and speed curves. Current = 10 amperes per sq. in. (4·375 amps. per brush); positive brush.

It was said both that there was a minimum voltage below which no appreciable current would flow, and also that the voltage-drop curves passed through zero. This has led the author to investigate this problem closely, both for a stationary and moving contact.

---

* See Bibliography, (8).

The results are shown in Figs. 2 and 3. Fig. 2 shows that for a stationary contact the voltage-drop curve definitely passes through zero and rises steadily and almost proportionally to the current up to about 0·2 ampere. Fig. 3, however, shows a very different result. Here we have a marked difference between the positive and negative brushes. With the negative brush it would be true to say that there is a voltage below which no appreciable current will flow, but this is not the case with the positive brush. If the ordinates of the two curves were added together to give a curve of combined drop, the voltage would rise very steeply up to 0·02 or 0·03 ampere per brush and the curve would be of such a shape as to justify the statement that there is a voltage below which no appreciable current will flow. Fig. 2 shows not the slightest indication of this minimum voltage. The effect is noticeable at all speeds and corresponds to the sudden increase in voltage-drop immediately rotation commences. This is easily demonstrated by turning the moving contact by hand whilst watching the voltmeter. It is rather doubtful whether this sudden rise is entirely due to relative motion, as the voltage commences to increase on the application of a tangential force to the ring before motion takes place.

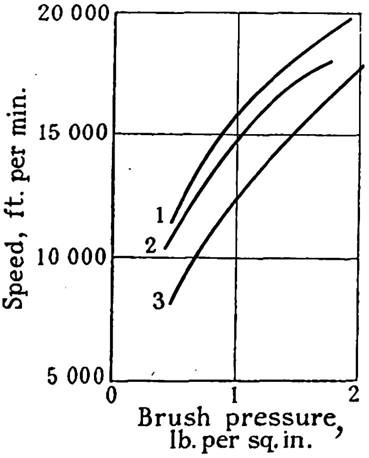

FIG. 6.—Instability curves.

Curve 1.—160 amperes per sq. in., 70 amperes per brush.
Curve 2.—40 amperes per sq. in., 17·5 amperes per brush.
Curve 3.—20 amperes per sq. in., 8·75 amperes per brush.
Positive brush.

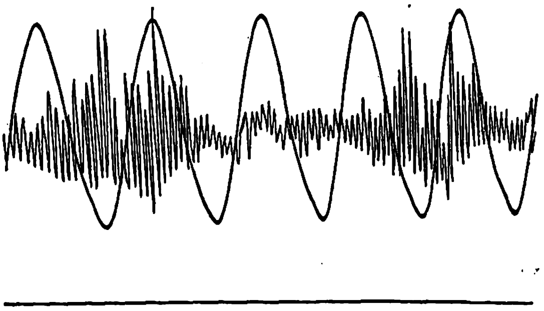

FIG. 7.—Speed = 3 300 ft. per minute; brush pressure = 2 lb. per sq. in.

Typical curves connecting voltage-drop and brush pressure are shown in Fig. 4. The voltage-drop is very high with low pressures and tends to a definite minimum at high pressures. These curves show the necessity of a high brush pressure to maintain low voltage-drop at high peripheral speeds.

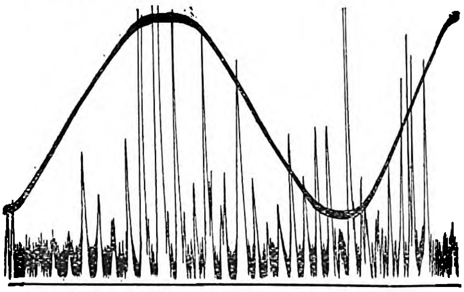

FIG. 8.—Speed = 9 900 ft. per minute; brush pressure = 2·5 lb. per sq. in.

Fig. 5 shows the change of voltage-drop with speed at various brush pressures. Up to a point the voltage-drop is practically constant, the general tendency being to rise slightly to a maximum and then fall somewhat before the final rise. This effect has been more marked in other results not shown here. The exceptional rise at high speeds is due to almost entire failure of contact of the brush and ring, caused by a high-speed intermittent contact and the formation of an air film between the brush and the ring. The fact that the speed at which the voltage commences to rise rapidly increases with brush pressure, led to an investigation resulting in the instability curves shown in Fig. 6. These were determined by fixing the brush pressure and then gradually increasing the speed until the voltage-drop showed a decided increase and a tendency to instability.

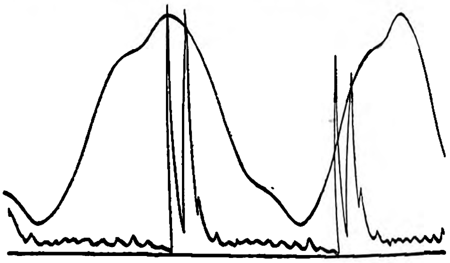

FIG. 9.—Speed = 9 900 ft. per minute; brush pressure = 4 lb. per sq. in.

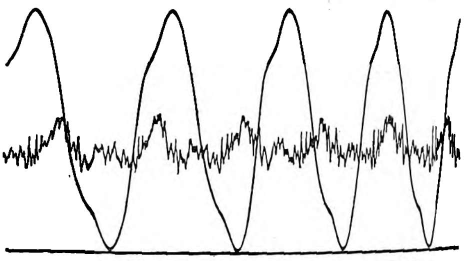

FIG. 10.—Speed = 12 100 ft. per minute; brush pressure = 4 lb. per sq. in.; rubber pad used.

It was found that an unstable voltage at a particular brush pressure and speed could be rendered stable by increasing the current. This is illustrated by the three curves taken at different current densities. As stated above, the instability is due to intermittent contact and it seems reasonable to suggest that the stabilization of the voltage-drop by an increase of current is due to the more vicious sparking retaining a low-resistance path between the brush and the ring for a greater portion of a revolution than is possible with the degree of sparking obtained with the lower current.

It has been observed that the coefficient of friction between a ring and a brush may decrease as the speed increases, and at the same time the contact-drop may increase. Two theories have been suggested to account for this.* The first suggests that an air film is drawn in between the brush and ring, and the second that an intermittent contact entirely accounts for the phenomenon. The originator of the second theory expressed the opinion that oscillograph records of the contact-drop at various speeds would tell us very much more clearly what is actually happening when current is being collected.

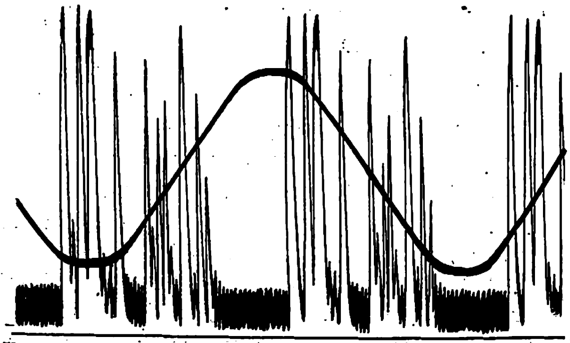

FIG. 11.—Speed = 9 900 ft. per minute; brush pressure = 1 lb. per sq. in.; rubber pad used.

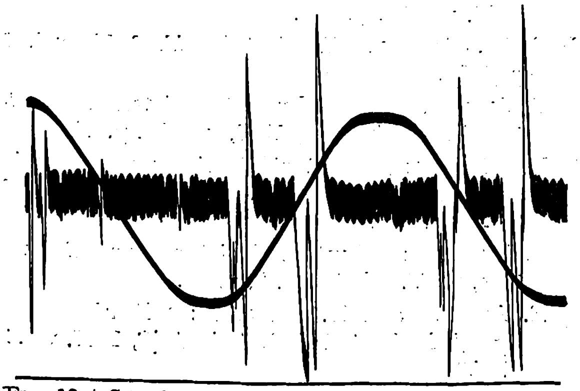

FIG. 12.—Speed = 9 900 ft. per minute; brush pressure = 1 lb. per sq. in.; rubber pad used.

Acting on this recommendation the author has taken oscillograph records and some of these are reproduced in Figs. 7 to 12. The oscillograms reveal the fact that the contact-drop is very unsteady and that the fluctuation increases with speed and decreases somewhat with increase of brush pressure.

Figs. 7 and 8 show the effect of speed on the fluctuation of voltage-drop. Each oscillogram was taken with a current of 23 amperes per brush. In Fig. 7 the brush pressure was 2 lb. per sq. in. and the speed 3 300 ft. per minute, and in Fig. 8 the pressure was 2·5 lb. per sq. in. and the speed 9 900 ft. per minute. In the former case the voltage-drop as recorded by a voltmeter was 0·9 volt and in the latter 1·6. In all the oscillograms a 50-cycle timing wave is shown. Figs. 9 and 10 illustrate the effect of increasing the flexibility of the connection between the brush and the arms applying the pressure. The current and brush pressure were in each case the same, and Fig. 9 shows a very bad case of intermittent contact giving a contact-drop (by meter) of 0·96 volt. This was entirely cured by inserting a small rubber pad behind the brush—Fig. 10 illustrates the result—the speed having been increased from 9 900 to 12 000 ft. per minute. The mean contact-drop was reduced to 0·55 volt.

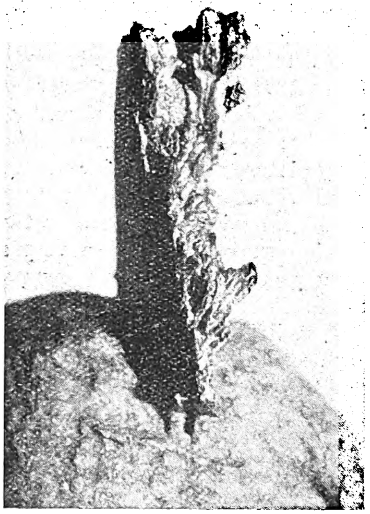

FIG 13.—Phosphor-bronze chip, 20 times full size. The dark plane on the left was flush with the surface of the brush. The chip is erected in plasticine to facilitate photographing.

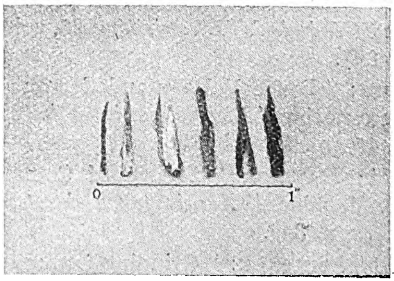

FIG. 14.—Phosphor-bronze chips removed from surface of brushes.

The change in character of the contact-drop fluctuation as it approaches instability is interesting and affords insight into the nature of the contact. Figs. 7 and 10 indicate the stable condition, and Figs. 8 and 9 show incipient instability. The last stage before complete instability is shown in Fig. 11—an oscillogram taken at 9 900 ft. per minute and 1 lb. per sq. in. brush pressure, the mean voltage-drop being 2·7 volts. There is no doubt about the intermittent nature of the contact. Fig. 12 depicts the unstable state—an air film has been produced between the brush and the ring, and contact only occurs once or twice per revolution. This phase developed from that shown in Fig. 11 with no perceptible change of speed, but resulted in the current falling from 23 to 2 amperes and the contact-drop increasing from 2·7 to something over 15 volts. In this state cyclical variation does not seem to take place as it was impossible to synchronize the oscillograph motor so that a steady picture might be viewed on the screen.

---

* See Bibliography (8), pp. 195 and 204.

The high peak values of voltage-drop are undoubtedly due to the brush breaking contact with the ring, or at any rate reducing the pressure to a very small value; but it is equally certain that the low points on the oscillograph record indicate good contact between brush and ring, and therefore we have an increased mean voltage-drop due to an intermittent contact. Nevertheless, if the speed is increased sufficiently or the brush pressure sufficiently reduced then an air film is established, as shown by Fig. 12, and the voltage-drop increases very considerably. This, however, must be considered to be an abnormal condition, and one under which only a small current will pass and very violent sparking takes place; no real contact can be considered to exist. The theory of intermittent contact is therefore the correct one and accounts for the rise in contact-drop and the reduction in coefficient of friction with increase of speed.

The author desires to acknowledge, with thanks, assistance rendered by Prof. C. L. Fortescue, O.B.E., M.A., and Mr. J. W. Sims of the City and Guilds (Engineering) College.

DISCUSSION ON

"AN INVESTIGATION OF EARTHING RESISTANCES." *

Messrs. P. D. Morgan and **H. G. Taylor** (*communicated*): *Electrical Endosmose.*—On page 737 the author states that "when the direct current flowed continuously . . . it was noted that the soil near the *positive* electrode was getting wetter and that near the negative electrode drier." Again, on page 738 it is stated that in another similar test the percentage of moisture was 7·1 per cent adjacent to the negative electrode and 16·5 per cent at the positive. On the other hand, on page 738, column 2, in the description of Fig. 5 it is stated that the moisture collected at the *negative* electrode, which appears to contradict the former statements if all the effects are to be ascribed to electrical endosmose. Fig. 4 shows a very large increase of resistance of the sample of soil after the passage of a small current for 50 hours. Part of this effect appears to be due to diminution of the total amount of moisture in the soil and part due to moisture movement. By using the figures given in Table 1 for change in resistivity of sandy loam with moisture content, and the stated values of the percentage moisture in the three sections after the test, it is estimated that the increase in resistance due to movement and evaporation of the moisture is less than 300 ohms, i.e. about 25 per cent. The actual increase in resistance recorded by the author, however, was about 320 per cent. A curve relating the percentage moisture to the distance from positive electrode, when extrapolated back to zero, indicates that the layer of soil touching the electrode is only sufficiently dry to have a resistance of twice its initial value. It seems clear, therefore, that the major part of the increase of resistance is due to some phenomenon such as the formation of gas films around the soil particles and on the surface of the electrodes. This is an important piece of evidence in connection with the comprehensive research which the E.R.A. is now carrying out on the problem of earthing in relation to power systems. The author's results suggest that an increase of resistance is to be expected with an earth electrode from which a current is steadily flowing to the soil, owing to electrolysis and to gradual moving away of the moisture. The figures given by the author for an earth plate (page 745) are 10 to 20 per cent, but some explanation is needed to account for these low results. Further work might well be done to find out whether, under any practical conditions, an increase of resistance takes place which is comparable with the 4 : 1 increase obtained by the author when using a tube containing soil. On the other hand the results show that, where a current is steadily flowing to an earth electrode from the soil, moisture moves in the same direction, and so tends to counteract the effect of the gas evolved from the electrolysis of the water. Whether sufficient water can be moved by this means to keep an electrode permanently moist, and keep its resistance low despite the gas evolved, is an interesting speculation which might repay investigation. The tramway system negative busbar earth plate is an example of a case where the current is always flowing towards the electrode. These results also indicate the errors which may occur from the use of direct current for measuring the resistance of earth electrodes. In connection with the author's second electrical endosmose experiment, it would have been interesting if, after obtaining a head of water of 9 ft. and a minimum current of about 36 mA, he had reversed the direction of flow of current and noted how its value changed as the head of water diminished. The result might have modified his view that "the phenomenon was one of mechanical back-pressure affecting electrical resistance in the same way as an electrical back-voltage." For the analogy to hold it would be necessary for the current to jump to a value in excess of that with which the experiment commenced, and then gradually fall to the initial value as the head of water diminished to zero. This seems hardly likely to take place.

Electrode Resistance Measurements and Comparison with Theoretical Values.—The author has been a little unfortunate in the piece of land he used for his tests on earth electrodes, and this renders difficult any comparison between the practical results and the expectations from theory. An example of this difficulty is seen in comparing the curves of Fig. 16 with the results shown in the second and third parts of Table 7. Both the tables and the curves refer to the variation in resistance with separation of 6 ft. by 1-inch pipes connected in series and parallel. If the values given are plotted it is found that the first three points fall on a curve similar to the theoretical curve (the difference in position of the two curves is of little account and coincidence would occur by selecting a slightly higher value of resistivity). The fourth point, however, upsets the curve entirely and this suggests that the resistance of electrode No. 5 is much higher than that of Nos. 1 to 4. This is confirmed by the fact that the resistance of No. 1 and No. 5 in parallel and 12 ft. apart, is greater than that of No. 1 and No. 2 in parallel and only 1 ft. apart. Unfortunately, the author does not give the separate resistances of electrodes Nos. 1 to 5. The value of experiments to determine the change of resistance with spacing is considerably diminished if the electrodes are not all of approximately the same resistance. In the case of the plate electrodes the theoretical values agree well with those obtained in the author's tests and it seems that, at least for these tests, the resistivity has been chosen correctly. From this it appears that in the case under consideration the average resistivity around a plate buried 6 ft. below the surface is about 10 000 ohms per cm^3. The decrease in resistivity with depth, referred to by the author on page 742, would therefore account for a value of 10 000 ohms per cm^3 being too low for driven pipes. Again, with the strip electrodes the curves plotted from theoretical and test values agree well in shape except for the fact that the theoretical value of 29 ohms given for the resistance between strips 16 ft. apart does not fit the curve well; 32 ohms seems more nearly the value. The large disparity in actual value is again accounted for by the fact that the resistivity of the soil is highest near the surface. The strips were buried at a depth of 1 ft. The author has given a large number of theoretical resistance curves, but the value of these is liable to be diminished on account of the large difference between the calculations and measurements for his own tests. We have shown above that there is probably a rational explanation for this difference and it seems that the results would have been more valuable, and greater dependence would have been placed on the theoretical curves, if the author had taken account of the variation of resistivity with depth.

---

* Paper by Mr. P. J. HIGGS (see page 736).

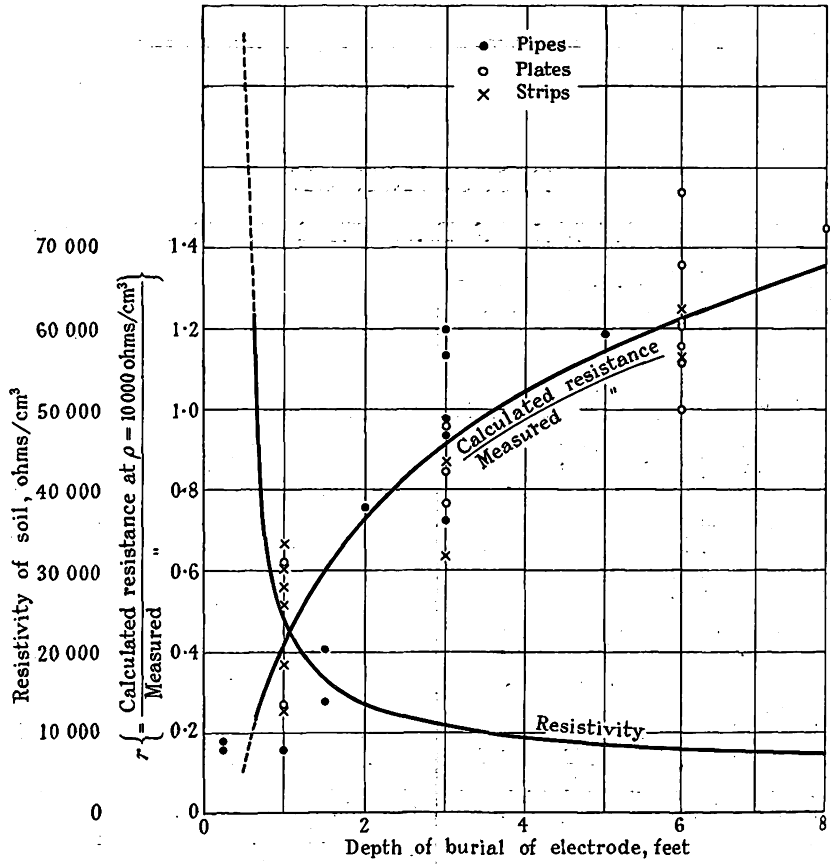

FIG. A.—Variation of resistivity and ratio of calculated to measured value of resistance with depth of electrode.

Variation of Resistivity and its Effect on Theoretical Values of Electrode Resistance.—We have calculated the ratio of the theoretical value of resistance to the mean measured value and find that for driven pipes this varies from 0·16 to 1·20, for plates from 0·27 to 1·54, and for strips from 0·26 to 1·25. In each case we have considered only the simple types of electrodes and have neglected the measurements for electrodes in series and parallel. These large variations are clearly due to changes in resistivity and it seems probable that these changes are in a large measure due to the varying depth of burial of the electrodes. We have therefore plotted a diagram (Fig. A) showing how the ratio varies with the depth, and, using the method of averages, have plotted the best curve to fit the points. (For the driven pipes we have assumed the depth to be half the length of the pipe.) It can be seen quite clearly that the ratio increases with the depth. It will also be noticed that the local variation of resistivity diminishes as the depth increases (see Table A). Fig. B shows how the ratio of the maximum to the minimum resistivity varies with depth.

TABLE A.

Depth	Maximum value of r	Minimum value of r	Ratio $\frac{\text{Max.}}{\text{Min.}}$
ft.			
1	0·67	0·16	4·18
3	1·2	0·64	1·88
6	1·535	1·0	1·535

On the assumption that the method of calculation used by the author gives a correct result, and since the resistance is proportional to the resistivity, we may say:—

$$\frac{\text{Calculated resistance of electrode (at } \rho = 10\,000 \text{ ohms/cm}^3)}{\text{Mean measured resistance}} = \frac{10\,000}{\rho}$$

Where ρ = actual average resistivity,

or $r = 10\,000/\rho$ . . . . (1)

$$\text{From (1)} \quad \frac{\text{Maximum value of } r}{\text{Minimum value of } r} = \frac{10\,000/\rho_{min.}}{10\,000/\rho_{max.}} = \frac{\rho_{max.}}{\rho_{min.}}$$

Therefore the last column in Table A and also in Table B is a measure of the variation of resistivity. From (1) the resistivity may be calculated for various values of r and hence, from Fig. A, for various values of the depth. This gives the curve relating resistivity to depth shown in Fig. A. It should be understood that these values of resistivity are based on mean values of resistance taken over a period of one year and that they are the mean values for the soil extending to at least 1 ft. on either side of a plate or strip. For a pipe, they refer to the mean value over the whole of its length. It would be interesting if the author could make direct measurements of resistivity at various depths to confirm this curve. The use of the values of resistivity obtained from the curve will bring the average value of the ratio of the theoretical to the measured value of resistance to unity.

TABLE B.

Type of electrode	Resistance		$\frac{\text{Calculated value}}{\text{Measured value}} = r$	$\frac{\text{Maximum value of } r}{\text{Minimum value of } r}$
	Measured	Calculated		
	ohms	ohms		
Pipes	39	46	1·20	7·5
	940	152	0·16	
Plates	13·1	20	1·54	5·7
	141	38	0·27	
Strips	24	30	1·25	4·8
	155	40	0·26	

Table B is obtained from the author's results and shows that by grouping them according to the type of electrode the ratio of the maximum value of r to the minimum varies from 4·8 to 7·5, and, if the type of electrode is disregarded, the figure is 9·7. If, however, the results are grouped as shown in Table A, according to depth of burial of the electrodes, and irrespective of their type, the figure is reduced to less than 4·2 in all cases. These figures represent the ratio of the maximum to the minimum resistivity. The resistivity varies both with locality and depth. Account has been taken of the latter factor, thus leaving only a locality variation, which, as stated, has a maximum value of 4·2 at 1 ft. depth and a much lower value at greater depths. It is clear, therefore, that the quality of the ground used by the author for his tests is not quite as bad as he inferred.

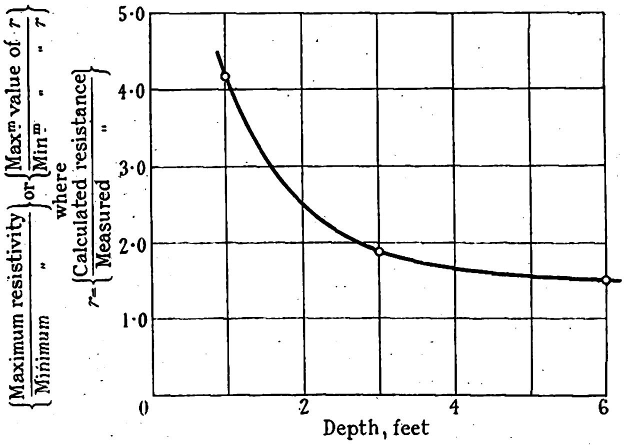

FIG. B.—Degree of variation of resistivity of soil at various depths.

Corrosion of Electrodes.—The author states on page 745 that the corrosion of an electrode may increase its resistance. This is contrary to the view of the Bureau of Standards,* who state that as a result of their tests, and also from the fact that rust layers formed in soil are permeable to water and are of no higher resistance than most soils, they have concluded that rust is of no effect in increasing the resistance of earth connections.

---

* "Ground Connections for Electrical Systems," Bureau of Standards Technological Paper No. 108, p. 9.

Mr. G. F. Tagg (*communicated*): A considerable portion of the paper is devoted to tests carried out on samples of soil dug out of the ground, such tests being carried out in the laboratory. These tests do give a considerable amount of useful information as to the variations in the resistance of soil with temperature and moisture content, and also investigate the effect of electrical endosmose. The resistivity so obtained cannot, however, be taken as an indication of the resistivity of the soil before it was disturbed. From tests which have been carried out to investigate this point, it is quite evident that disturbing the soil by taking it up alters the resistivity very appreciably. This, of course, is most likely due to the difference in packing. The measurements of the various types of earth connections were carried out either by the three-point method or by measuring the resistance of two electrodes in series, the resistance of one being known. In the case of the electrodes with which the author had to deal, the values of the resistances were approximately of the same order, and thus the three-point method doubtless gave satisfactory results. It is not, however, a method of measurement which would be recommended in practice, as it can only be safely employed if there are three earth connections available, the resistances of which are of the same order of magnitude. If it is necessary to employ temporary earths such as pipes driven 2 or 3 ft. in the ground, the method should not be used as the resistances of such pipes may be 50 or 100 times that of the earth plate being measured, and cases have been known where observational errors of quite a small magnitude, say 2 per cent, have produced as a final result a negative resistance for the earth plate. Such methods as the alternating-current fall-of-potential method or one of its modifications are much more satisfactory for general testing. In calculating the values of the resistances of the earth connections, the author has assumed a figure for the resistivity of earth of 10 000 ohms per cm cube, but there is no indication as to the reason for this assumption. It is surely evident, as in fact the author mentions in one place, that the variation in the resistances of pipes of the same dimensions is a definite indication that the resistivity of the soil is different in various localities. For pipes of the same size different resistances can only be accounted for theoretically by different resistivity of the soil, as is evident from the formula $R = \rho/(2\pi C)$. It would have been more satisfactory if the resistivity of the soil in the immediate neighbourhood of each electrode has been measured by the four-electrode method. A number of tests in the immediate vicinity of each electrode would doubtless have given a good average value for the resistivity of the soil immediately surrounding that electrode. This would have enabled the resistance of each electrode to have been calculated with a possibly closer degree of accuracy. There is another reason, however, for discrepancies in the resistances, particularly in the case of pipes driven in the ground. It is a very difficult matter to drive a pipe into the ground in a perfectly uniform manner, and in all probability the soil will be more tightly packed in some places than others, and in fact there may even be places where the soil is making no contact whatever with the metal of the pipe. If tests are made immediately the pipe has been driven or within a short time afterwards, the resistance obtained is certain to be higher than the calculated value. In calculating the values of the resistances of the various types of earth plates, the author has gone to considerable trouble in developing formulæ. It is to be noted, however, that these are all based on the formula for a driven pipe which is again based on an assumption which is not strictly true. A rather more simple formula which has been quite extensively employed in connection with driven pipes can be developed by assuming that the pipe, together with its image above the surface of the earth, forms an ellipsoid of revolution. Then if

l = depth in centimetres to which the pipe is driven into the earth,
d = the diameter in centimetres of the pipe,
ρ = the resistivity of the surrounding soil in ohms per centimetre cube,

the resistance R may be written

$$R = \frac{\rho}{2\pi l} \times \log_e \frac{4l}{d}$$

This formula is perhaps more easily handled than the one given by the author.

Mr. P. J. Higgs (*in reply*): I thank Messrs. Morgan and Taylor for indicating the need for two minor corrections. In the description of the endosmose experiments on pages 737–8, the words "positive" and "negative" regarding the electrodes should be transposed; the meaning is shown by the wording that "the effect . . . was one of movement of moisture in the direction of the current flow." In Table 9 the calculated resistance of the strips in series and 16 ft. apart should be 32 ohms instead of 29 ohms. It seems probable that the major part of the increase of resistance shown by Fig. 4 is due to an effect of gas films, as suggested. It is possible, however, that the layer of soil touching the positive electrode may have become very dry due to the combined effects of endosmose and of the heating at the high-resistance contact.

Account was not taken of the variation of resistivity with depth in the calculations in order that the results may be of general instead of local significance, for the variation would be appreciably different in different localities and would itself vary with the seasonal changes in any particular locality. A piece of land having normally a resistivity that decreased with depth may, for example, have the conditions actually reversed during a period of rain following a drought. It seems, therefore, that to have localized the theoretical calculations would have made the results possibly confusing or misleading in a wider sense. Local variations in soil resistivity should certainly be taken into account in practice as they are known to occur.

If the variation of resistivity with depth had been taken into account in the theory, the resistance measurements and the theoretical values would have more nearly corresponded. The measurements show, however—if the theory be assumed correct—a local variation in soil resistivity of over 100 per cent of a mean value at a depth of 1 ft. and of nearly 50 per cent at 6 ft., which percentages would probably have been greater if the measurements had been a single set of readings instead of the average of 7 sets covering one year. These percentages are the limits of accuracy to which the resistivity for the calculations could be taken, and they appear to be much too large for any useful purpose to be served in attempting to correlate the measurements with the theory.

The piece of land used for the tests was considered unsuitable mainly in so far as its surface layer had been disturbed for purposes of cultivation, this being the probable reason for the high locality variation in soil resistivity at shallow depths. The unsuitability was recognized at the outset but the land was the only plot available for the purpose. If it had not been previously cultivated, however, it seems reasonable to suppose that it would have still had the variations of the greater depths. To attempt a comparison, that would be more or less satisfactory, of theoretical values with any such resistance measurements would appear, therefore, to be in any case a very intricate undertaking.

The individual resistances of electrodes Nos. 1 to 5, averaged over the year, were 56, 43, 49, 44 and 92 ohms respectively. Such values, together with the particulars of the variation of resistivity with depth, would have extended the paper, which was purposely curtailed for publication. The suggestions made for further investigation may well be carried out with advantage.

It would have been of interest if Mr. Tagg had briefly described the tests that were carried out to investigate the effect of digging soil out of the ground on the soil resistivity, giving typical results. The methods used in this investigation for testing the electrodes were simple and reliable.

The subject of the correlation of the theory with the measurements has been discussed above, the remarks that follow being additional. The measurements were made to give typical values of earthing resistance and seasonal change, there being a paucity of published information of the kind with reference to this country. The theory was developed (in an Appendix) to indicate the relative inherent qualities for earthing purposes of the different types of electrodes that are commonly used —qualities that are quite independent of the vagaries of soil resistivity. This part of earthing technique seems to be of prime general importance and not to have previously been treated so fully. To indicate the inherent qualities it was necessary to assume a soil of uniform resistivity, and 10 000 ohms per cm cube was arbitrarily taken because it was a convenient round number as well as a representative value for the soil of the land used. Because the results of the investigation indicate that the soil resistivity varied appreciably with short distances in depth and locality; because the resistivity of the soil within a few feet of an electrode practically determines its resistance; and because the four-electrode method deals primarily with soil over a region of very much longer distances in locality and of many feet in depth, it is difficult to see how the four-electrode method could have been of material assistance in the correlation in the manner suggested. Laboratory tests on miniature electrodes in a homogeneous medium, such as water, would probably be more satisfactory in this respect than field tests.

The investigation was made on many electrodes, including several driven pipes, and, over a period of 3 years from the time they had just been installed, the measurements gave little evidence of any original discrepancies in resistance due to imperfect contact. The two formulæ—that given in the Appendix and that in the discussion above—for calculating the resistances of pipes are both based on assumptions that are not strictly true, and for similar reasons, and they give results that are within a few per cent of error of each other and, presumably, of the correct result. They would appear, therefore, to be about equally suitable. The theory used in the Appendix is, however, continuously applicable to pipes, strips and plates, and to any known arrangement of them. Assumptions that are not strictly true but are made to simplify otherwise extremely difficult mathematics and that give results within a small percentage error, should hardly seem untoward in problems of this nature.

INSTITUTION NOTES.

Letter from Kelvin to the late Dr. Kapp.

On pages 798 and 799 of the June issue (No. 402) of the *Journal* a facsimile letter was published which purported to be an original letter from Kelvin to the late Dr. Kapp, setting out the theory of the excitation of the field magnets of a dynamo.

The authenticity of the handwriting having been called into question by Mr. R. H. N. Vaudrey, the matter was investigated, with the result that it has been definitely acertained that the letter published in the *Journal* was a copy made by another hand and that the original Kelvin letter is in the possession of Mrs. Kapp.

"The Organization of the Electrical Industry in Great Britain."

The Institution has published in pamphlet form a paper by Mr. P. Good with the above title. It consists of a very full account of the organizations which exist to-day in the various branches of electrical engineering in this country. The information contained in the paper was collected for the use of the British National Committee of the International Electrotechnical Commission, and it has been considered desirable to publish it in a more readily available form. Any member of the Institution wishing to receive a copy should apply to the Secretary.

List of Members.

A new List of Members, corrected to the 1st September, 1930, is in preparation and will be ready about the end of October. Any member wishing to receive a copy should apply to the Secretary.

The Benevolent Fund.

On the last page of the cover of this issue of the *Journal* will be found an appeal for subscriptions, donations and legacies to the Benevolent Fund.

Annual Tables of Constants and Numerical Data.

A special reprint has just been published of constants and data relating to the subjects of Electricity, Magnetism and Electrochemistry, being extracts from Volume VII (1925–1926) of the above Tables, in which all explanations are given in both English and French.

The reprint (136 pages) has been compiled by Dr. A. Buffat, Mr. G. Durand (École Supérieure d'Électricité), Prof. G. Foex (Strasbourg University), Prof. R. L. Fortrat (University of Grenoble), Dr. N. Marinesco, and Prof. N. Thon (Jerusalem University).

Members of the Institution can purchase copies at the following reduced prices:

Cloth-bound copies: 60 fr. (10s.) instead of 90 fr.,

Paper-bound copies: 54 fr. (9s.) instead of 80 fr.,

on applying to the Secretary to the Publishing Committee, Mr. C. Marie, 9 rue de Bagneux, Paris VI^{e}, from whom full particulars can be obtained.

Purchasers will also be entitled to receive free of charge, until the stocks are exhausted, the corresponding reprints from Volumes III to VI of the Tables.

Proceedings of the Wireless Section.

82nd Meeting of the Wireless Section, 5th March, 1930.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 5th February, 1930, were taken as read and were confirmed and signed.

A paper by Mr. H. J. Lucas, Associate Member, entitled "Some Developments of the Piezo-Electric Crystal as a Frequency Standard" (see page 855), and a paper by Mr. J. E. P. Vigoureux, M.Sc., Graduate, entitled "The Valve-Maintained Quartz Oscillator" (see page 265), were read and discussed.

The meeting terminated at 7.30 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

83rd Meeting of the Wireless Section, 2nd April, 1930.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 5th March, 1930, were taken as read and were confirmed and signed.

A paper by Mr. R. H. Barfield, M.Sc.(Eng.), Associate Member, entitled "Recent Developments in Direction-Finding Apparatus" (see page 1052), was read and discussed.

The meeting terminated at 7.40 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

84th Meeting of the Wireless Section, 7th May, 1930.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 2nd April, 1930, were taken as read and were confirmed and signed.

The Chairman announced that the following nominations had been made by the Wireless Section Committee to fill the vacancies which would occur on the Committee on the 30th September, 1930:—

Chairman: C. E. Rickard, O.B.E.

Members of Committee: G. W. N. Cobbold, B.A., B. E. G. Mittell, G. Shearing, B.Sc., and E. H. Shaughnessy, O.B.E.

In the event of a ballot for the new Committee being required, Messrs. E. W. Moss and F. Tandy were appointed scrutineers.

A paper by Messrs. P. P. Eckersley, Member, and N. Ashbridge, B.Sc., entitled "A Wireless Broadcasting Transmitting Station for Dual Programme Service" (see page 1149), was read and discussed.

The meeting terminated at 7.20 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

DEVELOPMENTS IN MACHINE TELEGRAPH SYSTEMS AND METHODS OF OPERATION.

By H. H. HARRISON, Member.

[*Paper first received* 30*th December*, 1929, *and in final form* 22*nd January*, 1930; *read before* THE INSTITUTION 27*th March*, *before the* NORTH-EASTERN CENTRE 10*th March*, *and before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 17*th March*, 1930.]

SUMMARY.

The design and operation of machine telegraph systems has been very considerably affected in recent years by the production of high-speed communication links of the trans-oceanic order of length, and by new methods of operation on land lines enabling the line plant unit—the telephone pair—with its series loading and its repeater stations *en route* to be used for either the transmission of telegraph signals or speech, or both, simultaneously and independently.

The regenerative repeater, by enabling several sections of cable and land line to be interlinked, has given rise to methods of operation far-reaching in their effect both from the point of view of economy to the Administration and from that of reliability and speed to the user.

While the possibility of connecting two remotely situated medium-traffic offices over a single channel of a main-line high-speed multiplex system has been known for a number of years, this has not led to any considerable developments in that direction. Conditions are, however, arising in which medium traffic offices will use start-stop single-channel systems to an increasing extent, and this is being influenced by the large number of channels rendered available by the dual use of the land telephone cable. Wherever the telephone network extends, the telegraph network is ready to hand, and the single-channel system will, in course of time, replace the multiplex system for inland telegraphy.

The long-distance links with their regenerative repeaters require a precision in speed and phase control not necessary heretofore, and a study of this subject therefore forms a considerable portion of this paper.

The sending and receiving apparatus of the start-stop single-channel system are the inverse of each other, and the paper endeavours to establish a general underlying principle for the different variants described.

The last phase of machine telegraphy will certainly be that in which intercommunication between centres will be automatically effected and intermediate manual transmission avoided. This is possible by reason of the large number of channels available through the previously-mentioned dual use of the wire plant, and by the present-day standard of automatic switching technique.

TABLE OF CONTENTS.

Introduction.

(1) Speed and phase control.

Definition of synchronism; main-line synchronism; local synchronism; phase swing; detection of phase difference.

Motor speed control; classification of motors.

Governors. Baudot governor; D.M.O. governor; theory of Doignon governor; electro-mechanical governors; tuning-fork speed control; phonic-wheel motor; control of tuning forks; clock control of fork or reed rates of vibration; gang control of synchronous motors; inter-office speed control.

Phase control. Baudot's method; automatic phase-finding; action point; Picard's modification; Baudot epicyclic correction gear; Rothermel's corrector; Creed's correcting mechanism; Creed-Willson corrector; Wood's corrector; American corrector; Foll and Muirhead's corrector.

Methods of generation of correction impulses. Picard's correction from the signals; Western Electric method; Pernot's method.

Control of tuning-fork speed and phase by line signals. Heurtley and Foll's method; Bille's method; Angel's method; Potts's method; Connery's method; forward and backward correction of d.c. motor; Salmon's method.

Start-stop synchronism.

Local synchronism.

General principles of synchronizing schemes.

Speed and phase indicators. Fork speed adjustment; fork speed adjusted to speed of distant fork; Morkrum speed indicator.

Simultaneous speed and phase indicators. Western Union method.

Phase adjustment or orientation.

Construction of tuning forks. Carpentier's fork; Muirhead's fork.

Construction of phonic-wheel motors. Muirhead's motor.

Distributor construction. Western Union distributor.

Distributor speed.

Rates of vibration of tuning forks.

(2) Transmitters or composing machines.

General considerations; elementary keyboard transmitter; Siemens transmitter; alternatives to Siemens transmitter; all-electric keyboard transmitter; tape-controlled transmitter; Wheatstone transmitter; 5-unit code transmitters; Baudot's transmitter; Morkrum's transmitter; Potts's transmitter; Cardwell's transmitter; single-revolution clutches; modern start-stop transmitter; classification of tape-controlled transmitters; curbing arrangements; sending distributors; Riddle's transmitter; bell signalling on start-stop transmitters; overlap on keyboards; receiving perforator transmitter;

rational keyboard design; evolution of modern transmitter.

(3) The Translator or receiving mechanism.

General; the single selecting magnet; Baudot's methods; Sacco and Giacomini's distributor; Morkrum Baudot printer; Kleinschmidt's single-magnet distributor; Murray's single-magnet printer; Potts's printer; Kleinschmidt's single-magnet selector; interfering and non-interfering selectors; the Creed teleprinter; overlap of signal and stop pulses; inversion; curved code bars.

(4) Recent improvements to the Baudot system.

Murray's modifications; duplex operation; Booth-Willmot keyboard perforator; New Zealand Administration's modifications; Grünenwald speed and phase control of printer units; Verdan-Baudot anti-parasitic device.

(5) Regenerative repeaters.

Gulstad relay as interpolator; synchronous Gulstad operation; true regenerative operation; the Eastern Telegraph Co.'s regenerative system; the regenerative repeater and long-distance working; interworking of circuits with different numbers of channels; regenerative repeaters combined with voice-frequency transmission; effects of bias; the automatic scrutineer; regenerative operation on cable networks.

(6) Methods of operation of line plant.

Composite working; sub-audio telegraphy on telephone pairs; 2-power multiplex operation; morse multiplex telegraphy by division of line time; transposition of land-line Morse Code; duplex operation of long cables; 2-way working on loaded cables; distortion correction on long cables; channel reversing; automatic direction control.

(7) Start-stop machine telegraph operation.

General; all-electric systems; tape control of transmission; automatic transmitter control; bell signalling; overlap at receiving end; overlap at transmitting end; interlinking of start-stop system with duplex-multiplex circuits; mechanical distributors.

(8) The future of machine telegraphy.

Bibliography.

INTRODUCTION.

Since the previous occasion on which the author had the privilege of reviewing the subject of machine telegraphy before the Institution,* the development both in apparatus and in methods of operation has been extraordinarily intensive.

As the matter was then left, divergent opinions were held as to the respective merits of the 5-unit and Morse Codes, while radio telegraphy was relatively inferior to the land line or cable branches.

To-day, the employment of the 5-unit Code has been extended to transatlantic cables, while radio telegraphy has reached a position in which it has to be acknowledged as a serious rival to the older, established, means of long-distance communication.

The rivalry between wire and radio telegraphy has stimulated workers in both fields, with the result that submarine cables exist having a far greater traffic-carrying capacity than was ever thought practicable before.

This results from the early theoretical work of Vaschy and Heaviside and the practical work of Pupin and his co-workers, backed by the courage of the able minds controlling cable enterprises.

In the field of radio telegraphy the beam system of Marconi is fulfilling all the possibilities predicted for it, and the present position can be summarized by saying that we are now in possession of many communication links of the order of several thousand miles in length characterized by reliability and operating speeds held, until quite recently, to be impossible over such distances.

The centres of the world can be and are being linked up to a remarkable extent, and rapid communication with points, however remotely situated, has now come to be regarded as a commonplace.

The new conditions have reacted both on the design of apparatus and the refinement of methods. Thus, the high speeds now possible on transoceanic links have demanded a perfection in methods of synchronizing such that, by comparison, older methods are crude and inadequate. As in the transmission of still pictures and in television, synchronism is a fundamental requirement, so in modern machine telegraphy, where the object is to obtain a perfect picture of the transmitted signals, it is equally important.

Although the old method of allowing a small phase difference to accumulate at one end of the line and then correcting the distributor there is satisfactory for the comparatively short land line of a few hundred miles in length with a negligible distortion effect on the signals, it is not admissible for the long transoceanic or transcontinental link.

It is becoming increasingly necessary to run the distributors at as nearly equal speeds as possible so as to eliminate signal distortion by phase difference and to correct both ways by the passage of working signals. This involves speed control of a high degree of precision, and the speed must be frequently compared with some standard and adjusted to within the narrow limits allowed. This is only possible by reference to a master time-keeper—a clock—at both ends of the line, and the frequency of reference is as high as once per second.

Telegraph links can be indefinitely extended to-day, due to modern adaptations of the regenerative repeater invented by Baudot.

The combination of the vibrating relay principle of Gulstad with the regenerative repeater represents a new development of far-reaching importance. The relay can be so controlled that its vibrations are absolutely synchronous with the distant transmitter, an adjustment difficult to obtain in the ordinary way. The regenerative principle removes defects in the signals which would exist if the relay repeated directly, while the relay interpolates signals which would not get through with the regenerator alone. The interpolator-regenerator thus represents a new device resulting from a combination of old ideas, and it not only permits the formation of indefinitely long links but also secures greatly increased speed of operation.

---

* *Journal I.E.E.*, 1916, vol. 54, p. 309.

New methods of increasing the capacity of the line plant by the use of multiple frequencies and, more especially, the dual use of line plant for both telegraph and telephone purposes, will have an important effect on inland telegraph systems in the future; it represents a considerable part of the development which has been at once so rapid and so wonderful.

The object of this paper is to attempt to describe the various advances which have been made in machine telegraphs and their operation. A careful review of the different sections of the paper will force the student to the conclusion that of all the many contributors to the art of machine telegraphy, Baudot deserves the highest place. If he had left only the regenerative repeater behind him, the telegraph industry would have owed him a heavy debt, but he has been a source of inspiration to many of the inventors who succeeded him, and the designers of start-stop mechanisms in particular.

The author has to acknowledge information freely placed at his disposal by the late Mr. C. W. Schaefer, Electrician-in-Chief of the Eastern Telegraph Co., and by Messrs. K. L. Wood and Higgitt of the same company, relative to their regenerative system of cable operation. His thanks are also due to Mr. H. Kingsbury, European Plant Engineer of the Western Union Cable Co., to Mr. Sterling Morton of the Teletype Corporation of Chicago, the late Mr. C. F. Wilkins of Muirhead and Co., to Mr. J. V. Foll of the same company, and to Mr. A. Gibbs, Chief Telegraph Engineer of the New Zealand Post Office.

Section (1). SPEED AND PHASE CONTROL.

General.

The basis of all machine telegraph systems is synchronism.

The two aspects of this part of the subject are:

(*a*) Main-line synchronism, i.e. the synchronism between two revolving shafts at the opposite ends of a telegraph line, and

(*b*) Local synchronism. This is the synchronism required between distributor and printer units where the printer runs continuously and at the same speed as the distributor shaft, e.g. the Baudot and Rowland systems of machine telegraphy, while the same expression may also be applied to the Murray multiplex and its derivatives, in which the printing mechanism is released and completes the cycle of operation in the time of one revolution of the distributor brush arms.

It is to synchronism that we owe the possibility of the re-formation of distorted incoming signals and their retransmission—perfectly shaped with all errors removed. It is thus possible to link long land lines or cables together by means of repeaters, because signal-shaping errors are eliminated at each repeating point instead of being amplified and propagated.

Main-line Synchronism.—It is a comparatively simple matter so to adjust the angular velocities of the two rotating shafts at the end of a telegraph line that they are very close to one another, but a small, hardly measurable, difference of speed will give rise to a very appreciable difference of phase in a very short time. Practical synchronism therefore involves means by which the motors may be adjusted to a desired speed as closely as possible and held there. This is not in itself sufficient, and correcting means have to be added by which the cumulative phase difference is periodically destroyed.

In general, it is the practice to make one of the two shafts the standard, or time-keeping, shaft, and compare the speed of the other with it from time to time, making any necessary adjustments by means of some form of correction. The correction may be effected by varying the speed of the controlled shaft or adjusting its phase, or both.

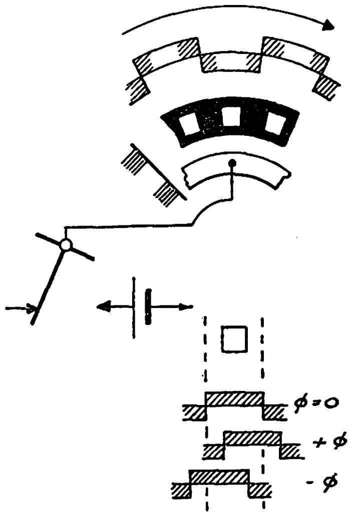

FIG. 1.—Influence of phase-swing on shortened segments.

It is usual to fix the speed of the controlled shaft at some definite fraction higher than that of the controlling master-clock shaft, and arrange for the gradually accumulating phase difference to determine a correcting influence before the phase error becomes large enough to mutilate the line signals.

For land-line working at speeds of 130 to 150 words per minute (5-unit code) phase differences of 1·25°, 0·9° and 0·75° per revolution have proved to be satisfactory. These correspond to speeds at the controlled end of 1·003, 1·0027 and 1·002 times those at the controlling ends.

Where great precision is required, it may be necessary to run at as nearly identical speeds as possible and then correct for phase deviation in either direction without appreciably affecting the speed. In addition, it is now being recognized that the integral effect of all phase corrections should be applied in such a direction as to vary the speed and make fewer phase corrections necessary. This refinement is not necessary on land lines of the length usually encountered, where there is ample margin; but on cable circuits, and more especially where two or more cables are interlinked, it is essential.

It is evident that, during running, the phase difference between the transmitted and received signals is continuously varying above and below the position of identical phase, and this phase swinging would cause overlapping of signals at the receiving end. Baudot recognized this and overcame the difficulty by shortening the receiving segments of his distributor, as shown in Fig. 1, thus retaining correct reception while allowing a phase error of $\pm \phi$.

It has been stated that the common feature of all synchronizing systems is the utilization of a slight deviation in phase to bring into operation forces preventing an indefinite increase in phase error. This is explained in a general way by Fig. 2. If the distributor brushes are running either fast or slow, these conditions can be represented by displacing the signal elements, as shown in the upper diagram. In addition to the signal-receiving segments, a set of correcting segments are provided, one pair for each signalling segment. The first of each pair, marked "F" in the diagram, are known as the "fast" segments, and the second, S, as the "slow." All the fast segments are multipled together, as are also the slow segments, and corrective forces are set up electrically in a variety of ways described later.

Motor Speed Control.

The first requisite of the motors employed is constancy of speed, the power required for the work to be done being usually insignificant.

There are three types of motor in use:

(1) Weight motors.
(2) Commercial-type electric motors.
(3) Synchronous motors with unwound iron armatures (phonic wheels).

Types (1) and (2) require some form of governor which will so adjust matters that a balance between the power applied to the motor and the power required to drive the distributor or other mechanism is maintained. The third type is driven by current impulses furnished from a vibrating reed or fork, the frequency of which is approximately constant over a fairly wide range of voltage variation and is only subject to slight creeping with variation of temperature.

The phonic-wheel motor is not capable of dealing with an appreciable load and hunts badly at about 0·01 h.p. For this reason it is sometimes combined with a d.c. motor, the speed of which is controlled by the same fork or reed as that driving the phonic motor itself. The constancy of operation of the one type is thus combined with the load capacity of the other, and two desirable features are thereby secured.

Such an arrangement is in use on the New York–Azores–Emden loaded cable.

Governors.

Baudot's Governor.—The centrifugal governor designed by Baudot is too well known to need description. Designed for Baudot apparatus and a standard speed of 180 r.p.m., it has given good service for nearly half a century.

D.M.O. Governor.—Recently (1925) a new type of governor which possesses remarkable properties has been developed for distributor speed control. Invented by two Portuguese telegraph engineers, Messrs. Mendonca and D'Oliveira, it has been constructed by the Ateliers L. Doignon of Paris, and is known as the D.M.O. governor. This governor is based on a principle the opposite to that which has hitherto been employed in nearly all printing-telegraph governors. The Baudot governor applies or withdraws an artificial load in accordance with the speed variation, so as to keep a balance between the load of the governed apparatus and the power supplied by the motor. In the D.M.O. governor, the power necessary to drive the apparatus at constant velocity is transmitted by the governor itself.

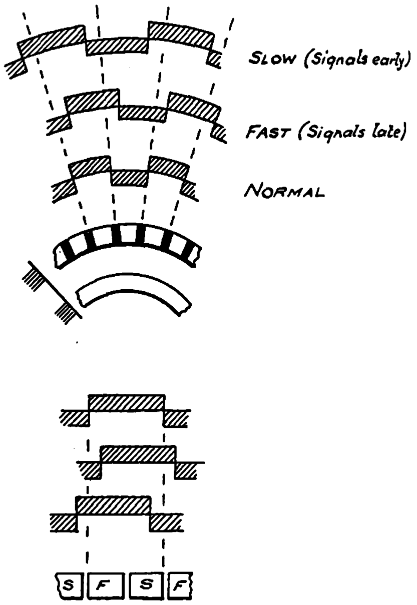

FIG. 2.—Generation of correction pulses from line signals.

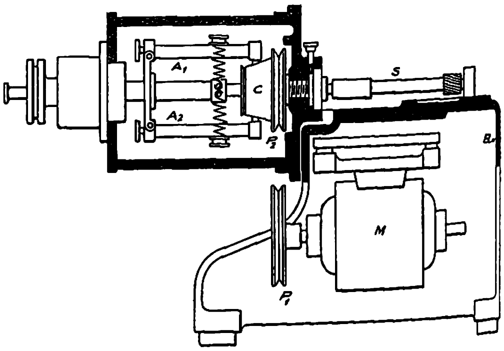

FIG. 3.—D.M.O. governor.

The construction of the governor, applied to drive a Baudot distributor by means of a commercial motor, is shown in Fig. 3. M is the motor carrying a pulley P_1, which drives shaft S through belt and pulley P_2, loose on shaft S. Pulley P_2 is coupled to shaft S through two arms A_1, A_2 pivoted at their left-hand ends to a cross-head solid with the shaft S. The right-hand ends carry friction pads which press with a certain force on the coned surface of P_2 by the agency of coiled springs.

As the motor M speeds up from zero speed, shaft S is carried round and follows the motor M, but when a certain critical speed is reached, slip is produced and S revolves at a constant speed regardless of that of the motor M.

The theory of the governor will be understood by reference to Fig. 4, which also represents an alternative method of construction.

Referring to Fig. 4, D_1 is a disc loose on the shaft S and carrying a pulley P driven by a belt from a motor (not shown). D_2 is a second disc rigidly connected to the shaft S and coupled to disc D_1 through friction pads "fp" mounted on the ends of two arms pivoted on D_2 which constitute the centrifugal masses of the governor. The two arms with their friction pads are kept up against the periphery of D_1 by a spiral spring, the tension of which counterbalances the centrifugal force of the masses "m." The friction coupling between D_1 and D_2 is proportional to the difference between the spring tension and the centrifugal force.

The power delivered

$$P_d = (T - m\omega_2^2 R)\mu R\omega_1 \quad . \quad . \quad . \quad (1)$$

where T = spring tension;

$m\omega_2^2 R$ = centrifugal force on the masses;
μ = coefficient of friction;
ω_1 = angular velocity of D_1;
ω_2 = angular velocity of D_2.

This power consists of two quantities:—

The useful power, $P_u = (T - m\omega_2^2 R)\mu R\omega_2 \quad . \quad . \quad (2)$
The power lost in heat, $P_l = (T - m\omega_2^2 R)\mu R(\omega_1 - \omega_2)$

Calling the resisting couple C, we have

$$\begin{aligned} P_u &= C\omega_2 \\ &= FR\omega_2 \quad . \quad . \quad . \quad . \quad . \quad (3) \end{aligned}$$

where F is the tangential resisting force.

Hence (2) can be written

$$P_u = (T - m\omega_2^2 R)\mu R\omega_2 = FR\omega_2$$

or

$$F = \mu(T - m\omega_2^2 R) \quad . \quad . \quad . \quad . \quad (4)$$

From the above it is seen that ω_2 is independent of ω_1. Also, from (4),

$$\omega_2 = \frac{T}{mR} - \frac{F}{\mu mR} \quad . \quad . \quad . \quad . \quad (5)$$

If the resisting couple is very small, ω^2 tends to approach $T/(mR)$. Obviously, to make ω depend as little as possible on F, F/μ must be small compared with T. This is done by using as large a spring tension as possible and a high coefficient of friction.

When these conditions are secured, then, as the critical velocity is reached, variations of ω_1 have no effect on ω_2, as shown by the curve in Fig. 4.

The speed of shaft S can be varied while running, by moving the governor arms A_1, A_2 (Fig. 3), backwards or forwards along the coned surface of the pulley. This increases or decreases T, and since matters are so adjusted that $\omega = \sqrt{T/(mr)}$ nearly, ω will vary as $\sqrt{T}$.

The results obtained with this governor are really remarkable. On the Lisbon–Oporto circuit *it* has maintained synchronism unfailingly, although the supply voltage to the motor at times varied between 30 and 40 per cent.

The French Government have reported its successful behaviour on the Paris–Lyons Baudot circuit and on the Paris–Lille sextuple Baudot circuit. Variations of voltage from 110 to 80 volts have not disturbed the distributor speeds. It has now been officially adopted by the French Administration.

Some 200 governors of this type have been fitted to the impulse sender mechanisms in the London automatic telephone system and have given satisfactory service.

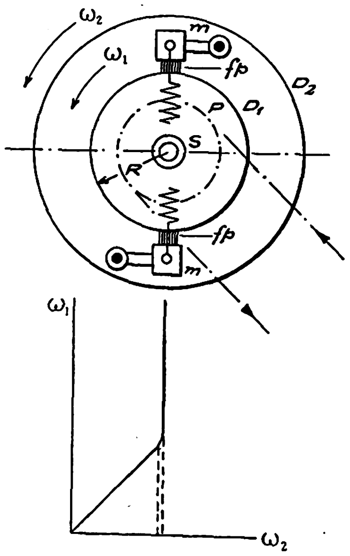

FIG. 4.—Theory of D.M.O. governor.

Governors, Electro-mechanical.—Fig. 5 shows an electrical method of speed control of a d.c. motor which depends upon a centrifugal governor. The motor shaft has mounted on it a disc D carrying a spring S loaded with a weight W. During the upper portion of a revolution of D, gravity acts against the centrifugal force of W, whilst gravity assists during the lower half of D's movement. S and W effect a short-circuit for half a revolution over the slip-rings SR on the resistance R_1, and the motor is accelerated and retarded periodically so that it runs at a certain mean speed.

In addition, the relay R is alternately operated and de-energized so that the pilot motor PM inserts and withdraws a vernier resistance R_2 in series with R_1. The weight W and spring S are so adjusted as to operate as described when the correct speed is attained. Any departure from normal speed varies the period of short-circuit, due to the weight-loaded spring S. If the motor tends to run fast the short-circuit is maintained when S is in the position shown in the diagram, centrifugal force overcoming gravity. If the motor runs slow the combined effect of gravity and centrifugal force is reduced and the period of short-circuiting is of less duration than when the speed is normal.

This method of speed control is due to the Lorenz Co. and is applied to high-frequency radio alternators. It is stated to give a regulation as close as 1 in 1 000.

Tuning-fork Control of Motor Speed.—The time-keeping properties of a tuning-fork may be utilized to keep the speed of a d.c. motor constant.

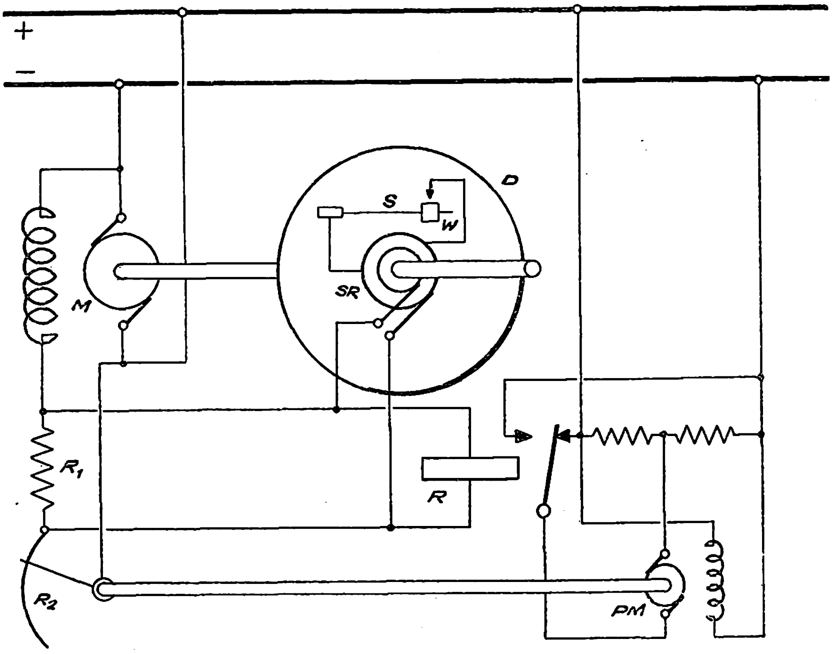

Fig. 5.—Electrical governor (Lorenz).

Fig. 6 illustrates an arrangement designed by the Morkrum Co. for speed control of a motor driven from d.c. supply mains. The fork induces alternating current in the secondary windings S of the transformer T. Two tappings are taken from the motor armature and led to slip-rings, by which they are connected through a lamp L to the secondary S of transformer T. If the motor runs at such a speed that the a.c. frequency generated is equal to the fork frequency, the fork will pull the motor into synchronism and it will operate practically as a synchronous motor. The motor speed is thus determined by the fork, and, since the fork frequency is very constant, the motor speed will remain constant also. The lamp L acts as a stabilizing load on the motor and also as a synchronism indicator. It burns steadily when the fork and motor are in phase and flickers when this phase relationship is disturbed. This arrangement, together with a phonic-wheel motor coupled to the same shaft and driven by the common fork, is the arrangement adopted on the Emden-New York cable previously referred to.

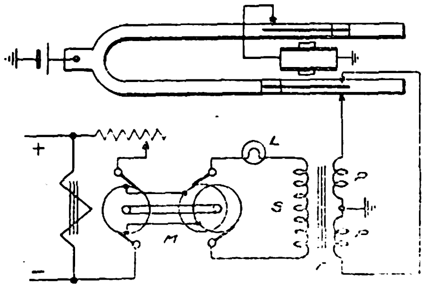

Fig. 6.—Morkrum fork control of d.c. motor.

Fig. 7 shows an arrangement due to Potts. The motor M is provided with a crown-wheel commutator C mounted on its shaft and provided with three brushes. The two outer brushes are joined to the pair of contacts controlled by one tine of the fork F. When the motor is running at the right speed, the number of contacts passed over by the central brush is the same as the number of half-vibrations of the fork in unit time. If the motor lags, the phase of commutator and fork contacts is upset and the resistance R is short-circuited, so that the current to the motor is increased.

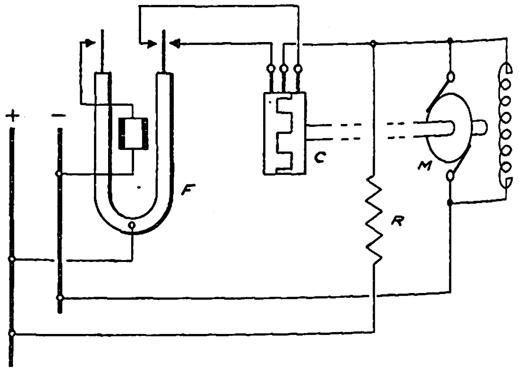

Fig. 7.—Potts's fork control of d.c. motor.

In the method shown in Fig. 8 a reed R drives a phonic-wheel motor PWM on the shaft of which is a disc D_1.

The d.c. motor is provided with a disc D_2. Each disc has a contact segment embracing a half-diameter. D_2 is set in advance of D_1 and, in the position shown, short-circuits a portion R_1 of the resistance $(R_1 + R_2)$.

Any variation of speed of DCM results in the period of short-circuiting being varied to retard or accelerate the motor.

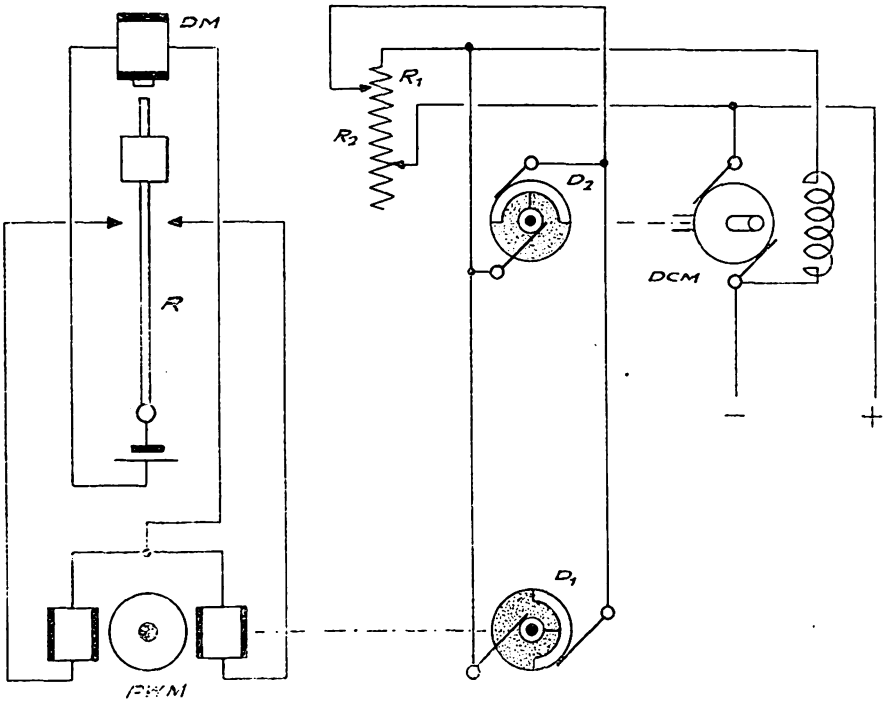

FIG. 8.—Phonic-wheel control of d.c. motor.

A method of accurately controlling the speed of d.c. motors, due to Mr. H. V. Higgitt of the Eastern Telegraph Co., is detailed in Fig. 9. Two multiple-segment commutators are swept over by brushes B_1, B_2 driven by the d.c. machine DCM and a phonic-wheel motor PWM, respectively. The brushes revolve at equal speeds through step-down and step-up gears. Normally, brush B_1 lags behind brush B_2, so that a certain number of resistance units are inserted in the field circuit of D.C.M. The phase angle between the brushes is determined by the voltage and the load on DCM. If this motor tends to lag, the phase difference increases and more resistance is inserted in the field. The reverse happens if it tends to accelerate. The speed is held at the desired point within the limits of the speed accuracy of the phonic-wheel motor. The motor DCM could be made to drive an alternator by which alternating current at a very constant frequency could be generated. Such an alternator could be of quite considerable power.

Phonic-Wheel Motor with Fork or Reed Control.—The phonic-wheel motor independently discovered by La Cour and Lord Rayleigh in 1865 is too well known to need description. Driven by a vibrating reed or tuning-fork it constitutes one of the best methods of furnishing the steady distributor speeds so essential to machine telegraphy. Although originally used by Delany and La Cour for morse multiplex systems, its energetic advocacy by Donald Murray has led to its adoption in England and America, and it has even penetrated to France, the home of the Baudot system.

The French telegraph engineer, Mercy, mentions its application to the Athens–Salonica quadruple circuit where the supply voltage varied between 180 and 240 volts. Salonica held Athens in synchronism in spite of the variable voltage, this being explained by the fact that a variation of 100 per cent in the energy supplied to the fork magnets caused, according to Mercy, a frequency variation of only 0·9 per cent. Mercy goes on to say that it does not require skilled attention and its maintenance is almost nil, and expresses the opinion that the phonic-wheel drive will render the Baudot system more practical and more robust and give more scope to its

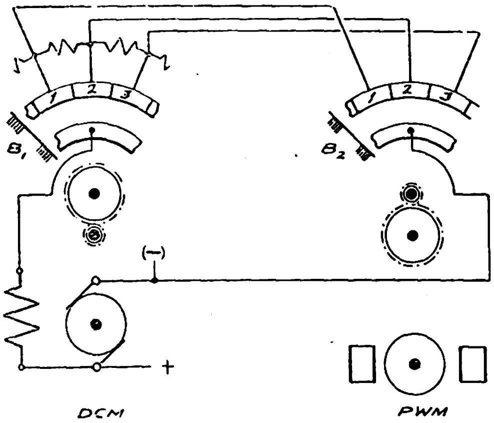

FIG. 9.—Higgitt's phonic-wheel control of d.c. motor

extension. This is in line with the experience of others.

As previously stated, the motor can be driven by either a reed or a fork, both of which possess identical properties and are equally satisfactory in use.

The explanation of the extremely satisfactory nature of the phonic-wheel fork-reed method of driving distributor brushes is simple. The motor is driven round tooth by tooth by receipt of current pulses fed to the driving magnets. So long as the rate of delivery of the pulses is constant, the motor revolutions are constant too.

The fork or reed can be constructed to have a natural frequency of vibration, which can be varied over a certain range by loading the tines with a weight or weights.

The rate of vibration of a fork or reed is subject to slight changes, due to the following external causes.

(1) Variation of current in driving magnet. If the driving current is reduced, the amplitude of vibration is reduced also and the rate of vibration is increased. The converse happens if the driving current is increased. The amplitude increases at the expense of the frequency.
(2) The adjustment of the driving contacts affects the degree of change in the rate of vibration. Variations in frequency are also caused by variations in contact pressure and chattering of the contacts, each of which effects changes in the driving force.
(3) Welding of motor-driving contacts and sparking at fork-driving contacts.
(4) Voltage variation.
(5) Temperature variation.
(6) Overload.

Under (1) it is to be noted that the rate of change of frequency is not the same when the fork-driving circuit is changed to decrease the frequency, as it is when it is changed to increase the frequency.

The effect of voltage variation is very slight, but temperature variation is more serious. The latter may be overcome by using Sinevar—a nickel-steel alloy with an almost negligible temperature-coefficient. Ordinary steel forks or reeds decrease their frequency by about 0·1 of 1 per cent per degree C. rise of temperature.

Control of Tuning forks.—The general method of driving a fork (wherever subsequently the term " fork " is used, " reed " is to be understood as being comprised also) is through a contact on one of the tines butting on a fixed contact suitably supported on the frame (Fig. 10*a*). The frequency of the fork is brought approximately to that desired by similar weights (not shown) on each tine, and a vernier adjustment is provided by the electromagnet SCM, the pole-pieces of which are opposite the tines when the fork is quiescent. The magnetic effect of SCM increases the stiffness of the tines of the fork and produces an increase in the rate of vibration. This increase can be regulated within sufficiently wide limits by adjusting the resistance R. The ammeter A is calibrated in terms of the fork frequency. The arrangement is due to the Western Electric Co. In Fig. 10(*b*) the same arrangement is proposed by Messrs. Muirhead and Co. as a means of driving the fork, the current pulses being furnished on both excursions of the fork tines to and fro, the tines being pulled into the normal position from either limit of motion. The advantage of this method of driving the fork lies in the fact that the fork is impulsed each time the tines move in and out, and it avoids the bias set up by the ordinary method where the tines are not vibrating in their normal position.

Small variations in frequency may be obtained by varying the gap between the tines and the driving magnet, which may also be slid along the tines, either above or below.

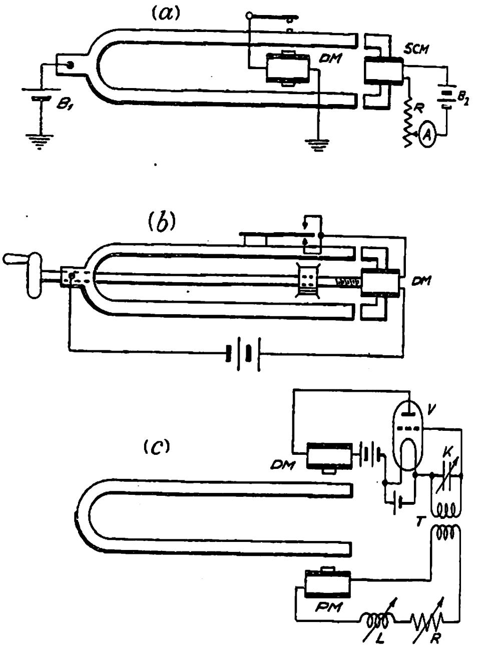

FIG. 10.—Three methods of tuning-fork control.

Fig. 10(*c*) shows a method of maintaining a fork in vibration by the use of a thermionic valve, and originates with the Western Electric Co. The operation of the arrangement is as follows: The fork is plucked to set it in vibration. An electromagnet PM with a polarized core acts as a generator and produces alternating current in the tuned circuit consisting of the transformer T, the secondary of which is also tuned. The voltage of this current is increased at the input terminals of the valve V, which, in turn, produces a considerable increase in the current through the driving magnet DM.

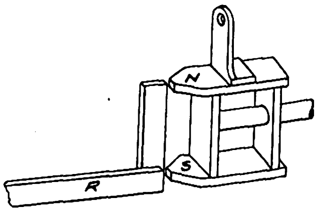

FIG. 11.—Higgitt's control of vibrating reed.

The phase relations between the current in PM and driving magnet DM are such that the generated current tends to maintain the vibration of the fork, which increases its amplitude until the energy dissipated becomes equal to the force supplied and the fork vibrates steadily at a given amplitude.

Fig. 11 shows Higgitt's method of controlling the frequency of a reed R of the Murray type. A small vertical steel piece is mounted on the free end of the reed and vibrates opposite the poles NS of two bar magnets mounted on a frame capable of oscillation. In the position shown the magnets act in the same way as the electromagnets of Fig. 10(*d*), and increase the stiffness of the reed. Its amplitude falls and the frequency rises. The control of the magnets may be reduced by rotating the whole system, thus weakening the effect on R and slowing it down.

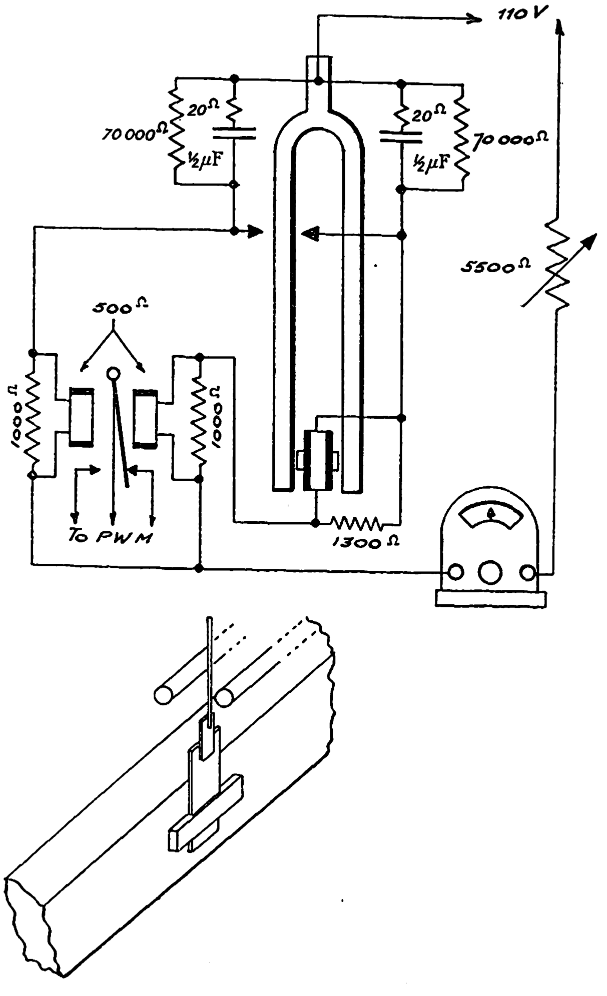

FIG. 12.—Muirhead's precision tuning-fork.

Fig. 12 represents a departure from practice by Messrs. Muirhead and Co. designed to give extreme constancy of frequency. Temperature variation has been met by the use of a non-temperature alloy for the tines. Frequency variation due to driving-contact spring control has been eliminated by dispensing with motor-driving contacts entirely and using the fork-driving contacts to control a relay which, in turn, controls one or more phonic-wheel motors. The type of contact employed is a 0·005 in. dia. platinum-iridium wire operating between two circular butts of the same material (see lower sketch of Fig. 12). The gap between the fixed butts is fixed, as variations of this gap affect the speed. The contacts are mounted on a carriage so as to be adjustable relatively to the moving-contact spring, which should be centrally between the fixed contacts when the fork is at rest. Sparking, even when scarcely evident, produces considerable variations in speed and this is eliminated by the spark-quenching circuits shown. The milliammeter is provided to keep the current to the fork-driving magnet constant. All causes of fork-frequency variation are eliminated as far as possible, and on a test lasting for several weeks the variation was found to be 0·0001 of 1 per cent with a maximum temperature difference of 26 deg. F. The advantages of this fork, as applied to synchronous telegraph working, are very considerable. When several regenerative repeaters are operated in series, there is phase variation due to distorted signals. By improving the constancy of speed at all points, the amount of correction necessary is considerably reduced. Four sets of tines are made, covering a frequency range of 400 to 4 000 cycles per minute.

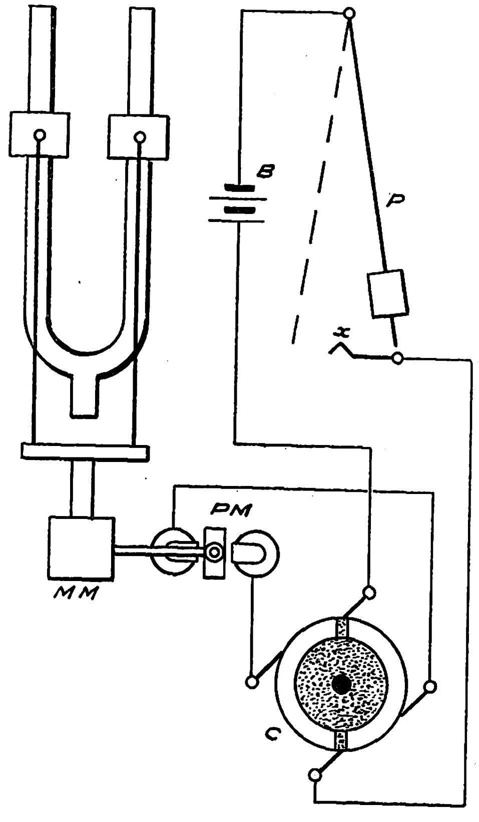

FIG. 13.—Brown's clock control of fork frequency.

Clock Control of Fork or Reed Rates of Vibration.—For a variety of reasons, dealt with later, motors of the phonic-wheel type when considered in connection with speed control of the type being discussed do not give an absolutely accurate control. S. G. Brown recognized this and brought out the arrangement of Fig. 13. Here the fork—driven by means not shown—has its frequency referred to a clock and its rate increased or reduced, depending upon the conditions indicated when the comparison is made. For this purpose the shaft of the phonic-wheel motor—not shown—carries a 2-part commutator C. The fork has two weights controlled by links so that they can be slid along the tines of the fork backwards or forwards, by the polarized relay PM and suitable mechanism MM. The operation of the arrangement is as follows: The relation between the to-and-fro swing of the pendulum and the revolution is such that if the speed of the motor is correct, i.e. it has made either one or an exact number of revolutions when the pendulum contact "x" is closed, the vertical brushes are standing as shown in the drawing and no circuit is closed for battery B. If the disc C is leading or lagging, the circuit is com-

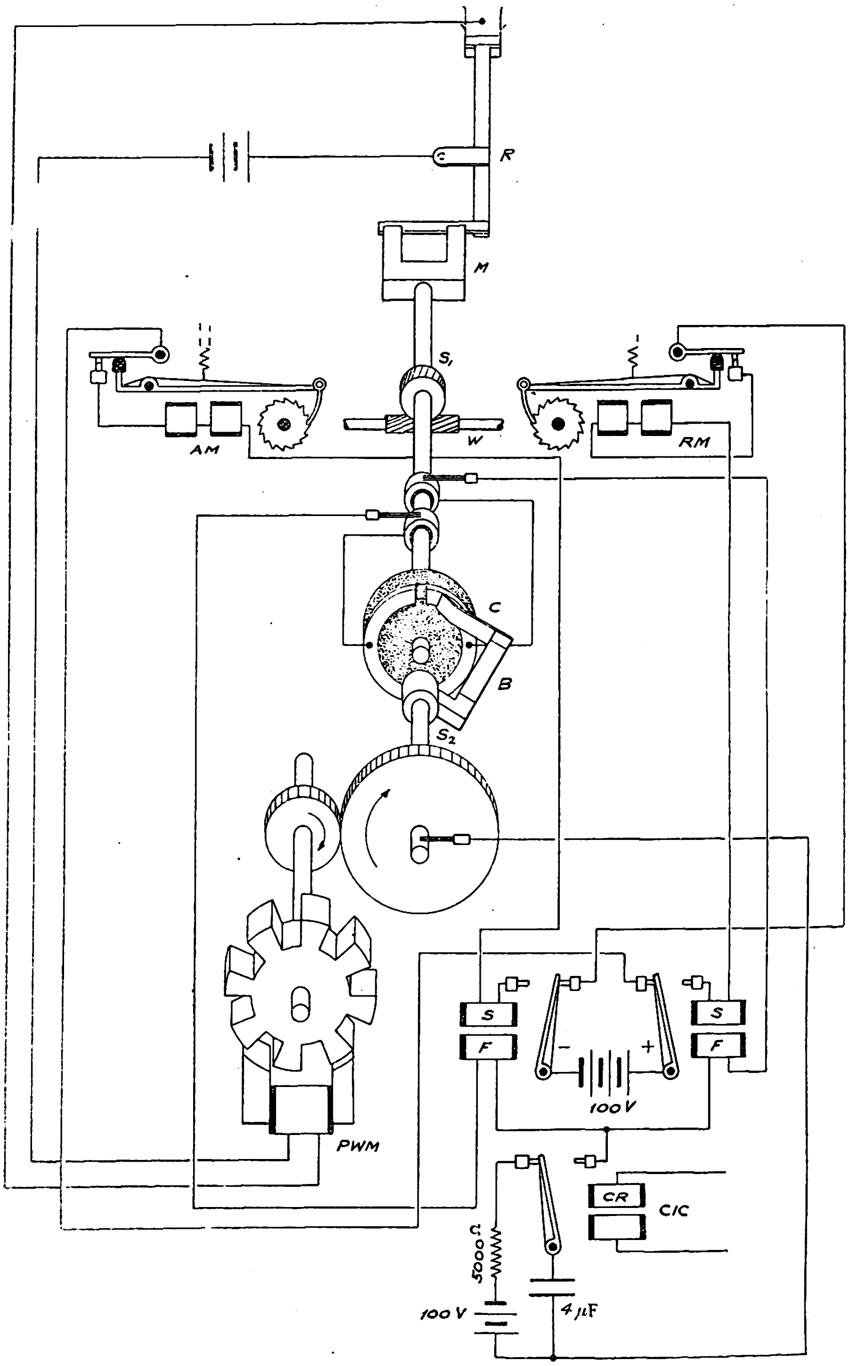

Fig. 14.—Eastern Telegraph Co.'s clock control of fork frequency.

pleted in one direction or the other through the polarized relay PM, and the weights are shifted to raise or lower the speed of the fork in accordance with the requirement which the position of C indicates. Since a good clock will keep accurate time to within a few seconds per day, the advantage of this method of fork-frequency control will readily be seen, and it furnishes means by which distributors in various offices remotely situated can be kept in very close synchronism with each other.

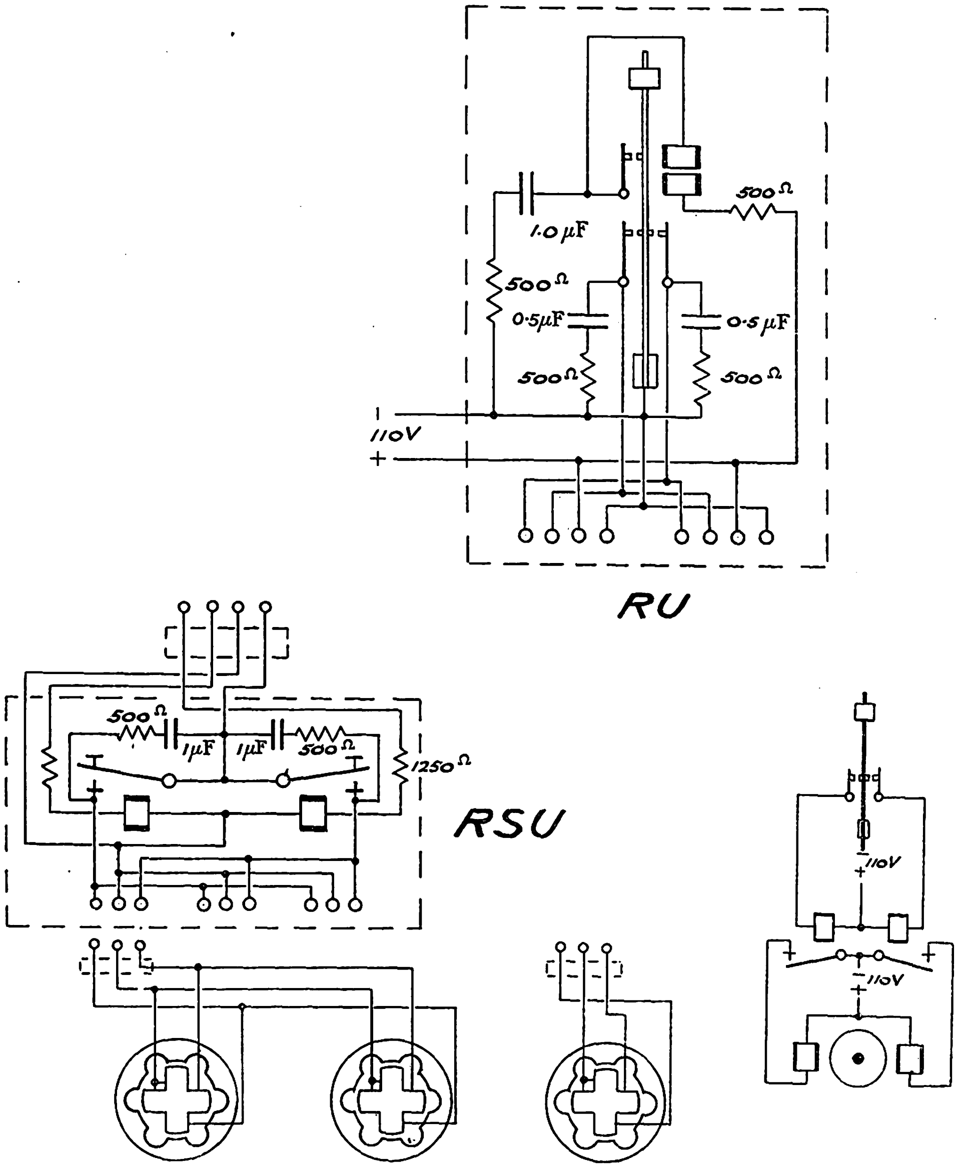

Fig. 15.—Eastern Telegraph Co.'s gang control of phonic-wheel motors.

The method of keeping the frequency of a reed or fork within narrow limits by periodic reference to a standard clock, as employed by the Eastern Telegraph Co. and invented by Higgitt, is detailed in Fig. 14. R is a reed, the driving contacts of which are not shown. M is a permanent magnet, the oscillation of which from time to time will, as previously explained, control the fork frequency at the desired value. The reed drives a phonic-wheel motor PWM which, through reduction gearing, rotates a brush B on shaft S_2 over a two-part commutator C. C is carried by a second shaft S_1 which carries the magnet M and is adapted to be rotated slightly in either direction by means of the worm gear W actuated by the two ratchet-and-pawl mechanisms shown. The brush B sweeps over the 2-part commutator C in 1 second and, if the reed frequency is correct will occupy a position midway between the two metallic segments on C at the end of each second of time. A Synchronome standard clock—not shown—sends out 1-second impulses over the clock impulsing circuit CIC in which there is included a correcting relay CR. In the normal, unoperated position of the armature of this relay, a 4-μF condenser is charged to 100 volts through a 5 000-ohm resistance. When the seconds impulse is received the armature of CR moves to its front contact and partly completes a circuit for the condenser to discharge through the flick magnets F of the two relays immediately above CR. If B has completed 1 revolution in 1 second, there is no path through which the condenser can discharge. If, however, the reed frequency is too high then B will be on the right-hand segment of C and the condenser will discharge through the flick magnet of the right-hand relay. The latter operates and closes a circuit from positive pole of 100-volt battery, its operated contact, stick or holding winding S, the magnet of the retarding mechanism, RM, contacts of armature of the latter, back contact of left-hand relay to negative pole of battery. RM operates over the circuit just traced, and its pawl moves its associated ratchet wheel and thereby the worm wheel W so that M is moved from the position shown to one where its control on the amplitude of R is reduced. The amplitude of R is increased and, therefore, its frequency is reduced. Subsequently, if R is running slowly M is moved back by the advance magnet AM. When either magnet operates fully it breaks down its own circuit and that of the stick circuit of its controlling relay. The two latter are interlocked through the back contacts of their armatures so that they cannot be operated at the same time if the correcting discharge current should divide between the two flick coils.

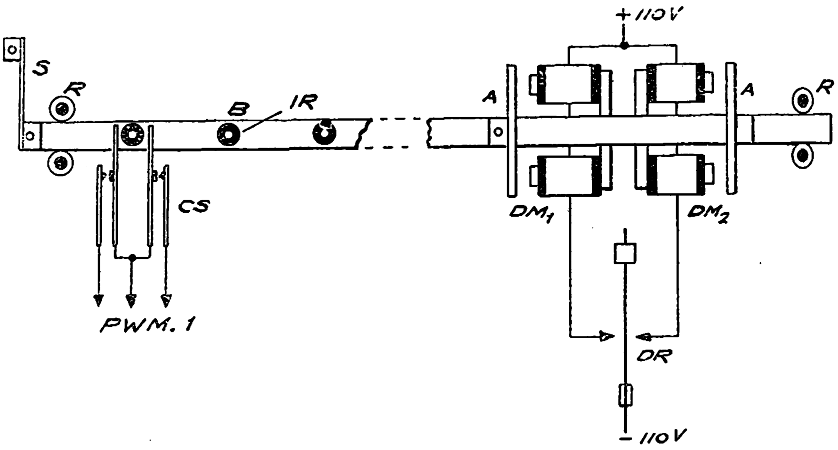

FIG. 16.—Method of gang control for phonic-wheel motors.

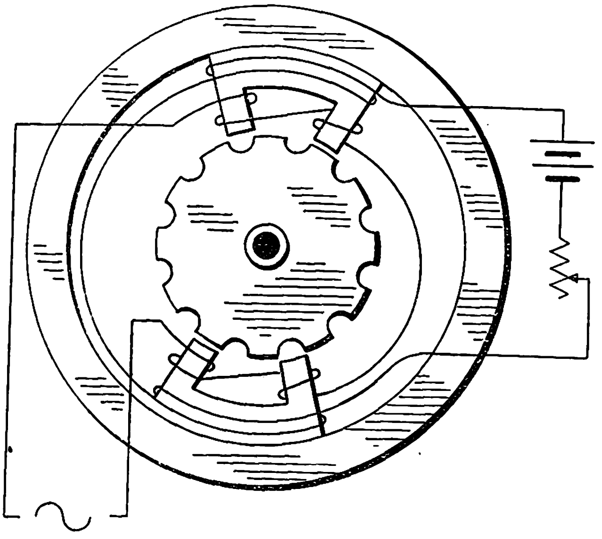

FIG. 17.—Polarized phonic-wheel motor

It will be seen that by the adoption of the clock control method just described it is possible to keep phonic-wheel motors at stations remote from each other running at speeds very closely identical, by means of the constant check on their driving reeds or forks. A standard clock such as the Synchronome will, if properly adjusted, keep correct time to within a second or so per day, and this gives some idea of the important step due to Higgitt's invention. The reed or fork has inherent time-keeping properties and on these is superposed a very accurate time control which takes account of slight frequency creeping due to any of the causes previously referred to.

Gang Driving of Synchronous Motors.—The speed control of a gang of phonic-wheel or other types of synchronous motors is divided into two broad aspects as follow:—

> The gang speed control of the motors in a single office.
>
> Interlinking gang-controlled motors in two or more offices.

The Eastern Telegraph Co. have done a considerable amount of work on the speed control of a gang of motors in one office, and Fig. 15 is an outline of their arrangements. RU is one of several reed units, the frequency of which is controlled by reference to a standard clock. Each reed unit is provided with connecting sockets by which it can control two reed sounder units RSU. Each of these units RSU has three parallel connecting sockets on the first of which it is customary to plug up two motors, and one on the second, leaving the third spare. The connections and operation of a phonic-wheel motor will be clear from the small sketch at the lower right-hand corner of the figure. By this arrangement one controlled reed can furnish driving pulses to 8 phonic-wheel motors. The author has seen this system in operation and is of the opinion that the arrangement is extremely efficient and reliable.

Another method of distributing constant-frequency pulses to a number of mechanisms is shown in Fig. 16. It consists of a bar B supported on rollers R and reciprocated by two sets of driving magnets DM_1 and DM_2, alternately energized by a vibrating reed DR. Along the bar and on both sides are placed, suitably spaced, insulating rollers IR adapted alternately to close pairs of contact springs CS which, in the diagram, are shown as controlling phonic-wheel motors.

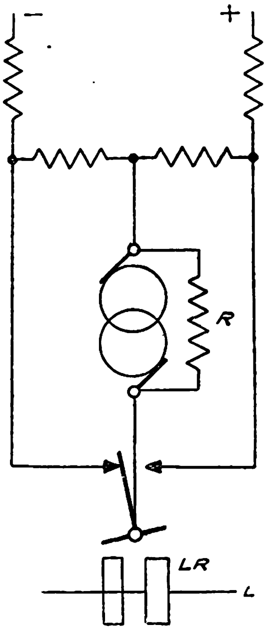

Fig. 18.—Inter-office control of synchronous motor.

By polarizing the driving magnets of a phonic-wheel motor as in Fig. 17, the motor can be run from a.c. supply mains. A better arrangement would be to use a closely governed motor-generator such as Higgitt's arrangement indicated in Fig. 9. In this way the phonic wheels of a large telegraph office could be controlled without employing either forks or reeds. This is in the direction of reduction of maintenance and operating costs, and is worth consideration. The polarized phonic-wheel motor for direct connection to supply mains was invented by Favarger in 1902. He used permanent magnets instead of the polarizing winding shown in the figure.

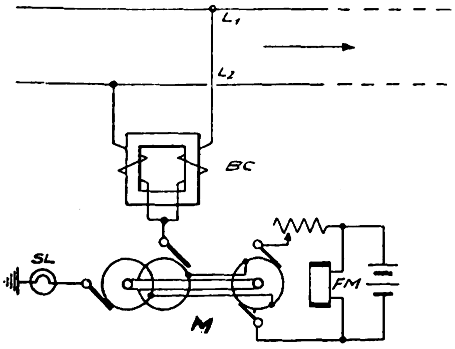

Fig. 19.—Synchronizing of motors over line wires.

It is clear from what has been said that the speed control of a number of synchronous motors in one office is not only possible but is quite practicable, and that its advantages require no emphasis.

Inter-Office Speed Control.—Inter-office speed control can be effected either by

> Transmission of impulses over a wire between the two offices or
>
> The clock supervision adopted by the Eastern Telegraph Co., previously alluded to.

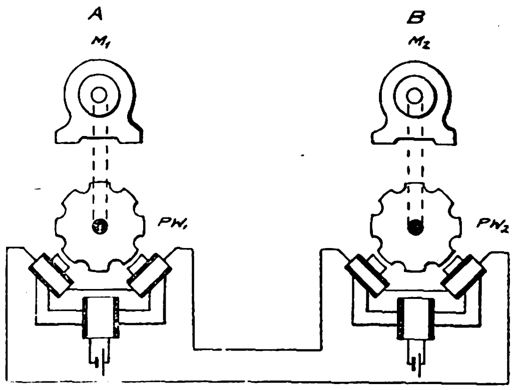

Fig. 20.—Synchronizing of motors over line wires.

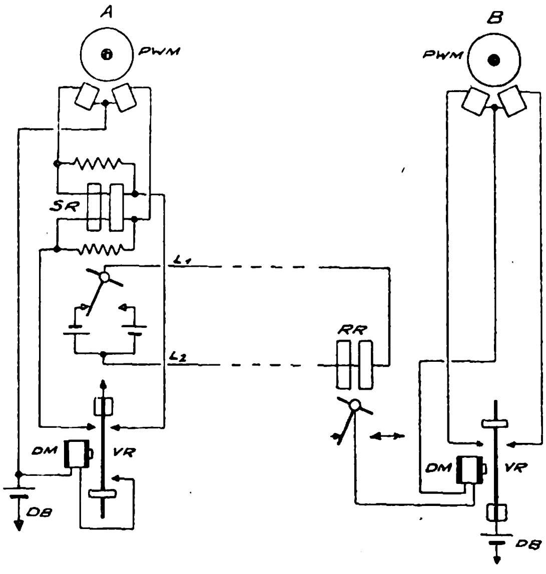

Fig. 21.—Remote control of phonic-wheel motor over line wires.

The simplest way to control a distant office by wire is to send out positive and negative pulses alternately from a master distributor at the one office over a line exclusively reserved for the purpose. At the distant end the oscillations of the relay tongue give rise to similar positive and negative currents in the armature of a synchronous motor, as will be understood by reference to Fig. 18. R is shunted around the motor to minimize sparking at the relay contacts. The motor of Fig. 17 could obviously be substituted for that shown. Fig. 19

is an arrangement described by Captain Poirson of the French Army. It was used in connection with a system of secret telephony which was effected on the two wires L_1, L_2. The motor armature of the motor M is tapped at two diametrical points and led to slip-rings. The alternating current passes over the two lines in parallel and is the synchronizing means by which a similar machine at the second station is controlled. The bridging coil acts as a choke to the telephone currents circulating round the circuit, while the lamp SL is a synchronizing indicator. This system has been successfully operated over a line, 615 km long, between Paris and Bordeaux. The frequency of the synchronizing current (only a few mA) was 50 cycles. It is stated that the system is eminently stable and will run into synchronism very rapidly.*

An arrangement of Siemens and Halske is illustrated in Fig. 20. Two motors M_1 and M_2 are directly coupled to phonic-wheel motors PW_1 and PW_2. By means of the polarized field magnet system the phonic wheels act as generators, and any departure from synchronism gives rise to synchronizing currents tending to pull the two systems into step.

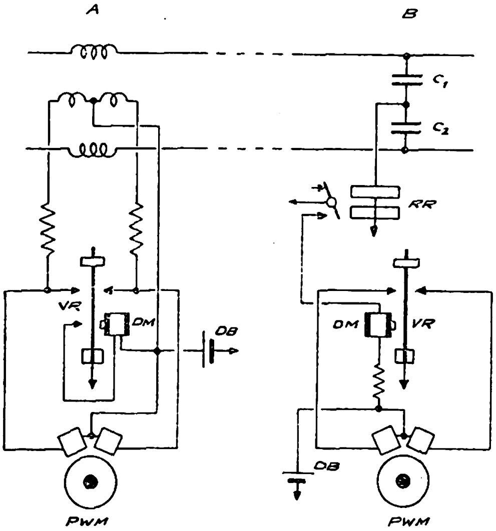

FIG. 22.—Remote control of phonic-wheel motors over line wires.

Fig. 21 represents a reed VR at a station A controlling a phonic-wheel motor there and also a relay SR by which alternating current is sent over the metallic circuit L_1 L_2. At the station B a receiving relay controlled by the reed at A drives the reed at B at exactly the same rate as the control reed. The two synchronous motors at A and B will thus be in step.

In the arrangement of Fig. 22, the driving pulses from the reed at station A are sent over the two lines in parallel. The arrangement scarcely needs description, but has the advantage over the previous one that the line circuit can also be used for signalling purposes. The two arrangements are described by Messrs. King and Barnes.†

The advantages of inter-office control and group driving are very considerable. Under certain circumstances synchronism can be maintained without the necessity for correction. Individual forks or reeds can be dispensed with and a great deal of adjustment saved, with decreased liability to faulty operation of the individual circuits.

Inter-office speed control may be accomplished by superposing the impulses on existing circuits, as has been shown, or the clock-control methods of the Eastern Telegraph Co. can be adopted.

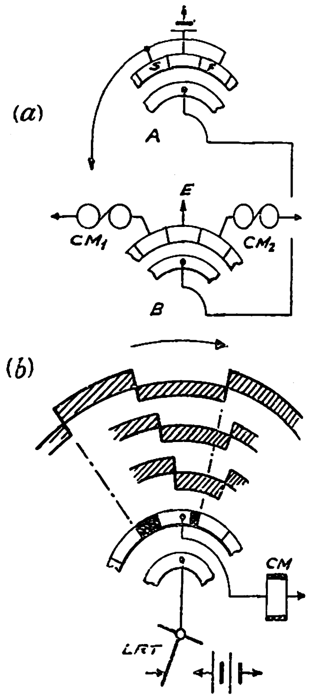

FIG. 23.—Method of effecting correction by special signals (Baudot).

On many land-line circuits the use of inter-office speed control will enable all correction arrangements to be abolished, provided that synchronous motors are used and all hunting is eliminated at the controlling end. With clock-control, correction from the signals will be necessary, although the frequency of correction will be very much reduced. The speed-difference between the two ends of the circuit tends to zero, phase-swinging becomes small in amount and the cycle of change is very slow. As a result there is less need to provide for shortened segments or land-line circuits and the number of segments may be increased, leading to higher speeds

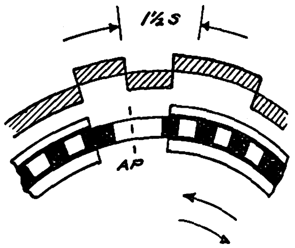

FIG. 24.—Position of receiving segments with respect to "action point."

---

* See Bibliography.

† *Ibid.*, (26).

of transmission, or, alternatively, if the segments remain at the same number the operating margin will be increased.

Phase Control.

Phase control or correction may be effected:—

By special correcting impulses sent out from the controlling station, or

By correcting impulses generated from the letter signals sent out from the controlling station.

The first method is applicable only where the alphabet is an equal-letter one, such as the 5-unit. Wherever an unequal-letter alphabet, cable or land-line morse is employed it is not practicable to employ special correcting pulses, since these must occur at an invariable part of the signalling cycle and the letter signals are of variable length.

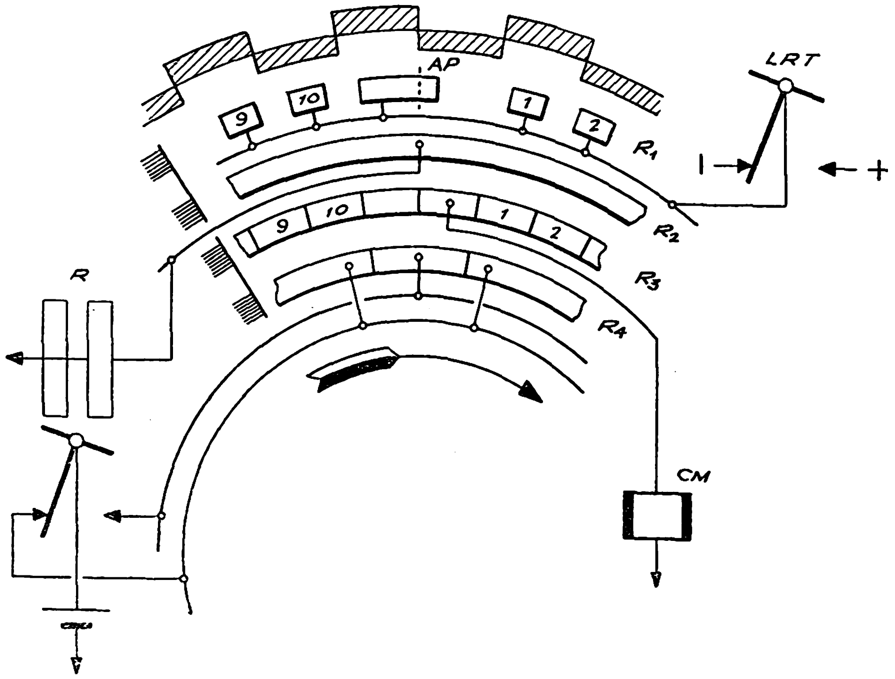

FIG. 25.—Picard's improvement on Baudot's correction.

Baudot's Method.—Fig. 23(*a*) shows an early method of Baudot. The part only of two distributors at stations A and B devoted to the maintenance of synchronism is depicted. Ignoring line lag, if exact synchronism exists the earthed battery at A connected to the segment intermediate between the two earthed segments S and F will send out a current pulse which, at B, is received on the earthed segment shown there. The current pulse from A exercises no corrective effect and, by assumption, this is not necessary. A is the time-keeping station and if B should, at the correcting period, be in advance of or lag behind A, the correcting pulse will be diverted to either of the correcting magnets CM_1 or CM_2, as the case may be.

Forward and backward correction is not now used on land lines, and the general practice, as previously explained, is to make the speed at station B slightly faster than at A and employ backward correction by means of one correcting magnet CM, as shown in Fig. 23(*b*).

Action Point.—As B creeps forward, indicated by the phase displacement of the received signals, the reversal from positive to negative takes place at a certain part of the correcting segment such that the time of contact is long enough for the local circuit closed by the line relay tongue LRT to operate the correcting magnet CM. As indicated in the diagram, this action point (*point de repère*) is reached after the third revolution. When correction takes place, the conditions shown in the first revolution (outer set of signals) are re-established and the cycle repeats. It is clear that, by moving the receiving correcting segment backwards or forwards, the number of revolutions between corrections will be reduced or increased. In practice matters are so arranged that the correction is effected about every 2 revolutions.

Automatic Phase-finding.—An advantage of employing special correcting signals, as described, is that in the event of disturbance to synchronism the distributor will " run in " automatically with the signalling channels in phase with those at the distant station. This cannot happen where more than one correcting point exists during a revolution, as the probability of " running in " at any one such point is equal and provision has to be made for " phasing," i.e. adjusting the channels to be in phase with the corresponding ones at the far end.

It has been usual to make the correcting segment movable and so adjust its position that corrections occur at the rate of about 1 per 2 revolutions. The receiving segments must then be so orientated that the middle point of these has a definite relationship to the action point. This is seen in Fig. 24, where the positive and negative correcting impulses are followed by a letter signal. Since, as previously explained, the shortened receiving segments should be placed in the middle of their signalling pulses, the middle point of the first of them must therefore be 1½ segments' length from the action point. In order that this may be done, the groups of 5 segments of each channel are mounted on slides, so that they may be rotated backwards or forwards to meet the above condition. This also necessitates the determination of the action point—a troublesome and time-taking operation.

The New Zealand Administration have abolished this procedure, and the correcting segment is fixed. The distributor runs-in automatically and the receiving segments are orientated until the receiver fails in both directions, the segments being fixed in the position midway between both extremes.

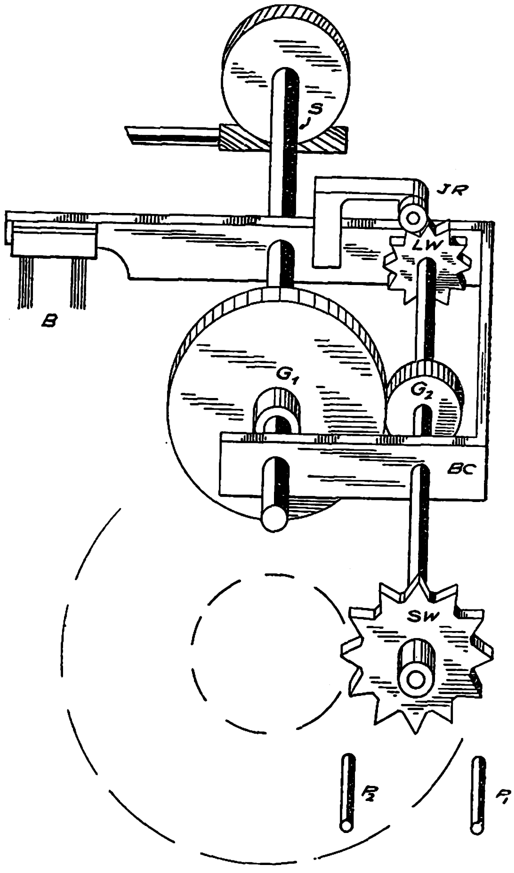

FIG. 26.—Baudot's epicyclic correcting gear.

Picard's Modification.—The arrangement of Fig. 23, in which the line relay actuates the correcting magnet directly, is not altogether satisfactory. The sensitiveness of the correcting magnet varies, being greater on frequent corrections than when these are relatively few in number. Consequently, the point at which correction is effected will vary, leading to under- or over-correction as the case may be. The correction of phase due to the correcting mechanism is constant in amount each time it is operated. When the correcting magnet is in an extra-sensitive condition, the mechanism may, be operated before the action point on the correcting segment is reached (over-correction). If, however, the correcting magnet is sluggish, the action point may have been passed over before the magnet operates, and the constant correction imparted by the mechanism is insufficient. In other words, the action point is subject to small variation, and although this causes little trouble on land lines where the margin is relatively large, it is a source of trouble on submarine cables. The

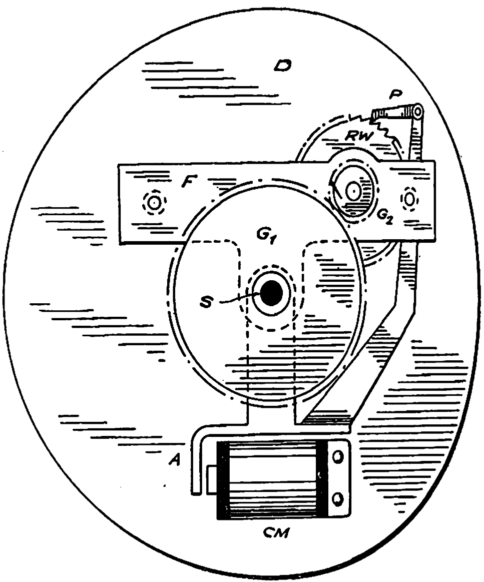

FIG. 27.—Rothermel's epicyclic correcting gear.

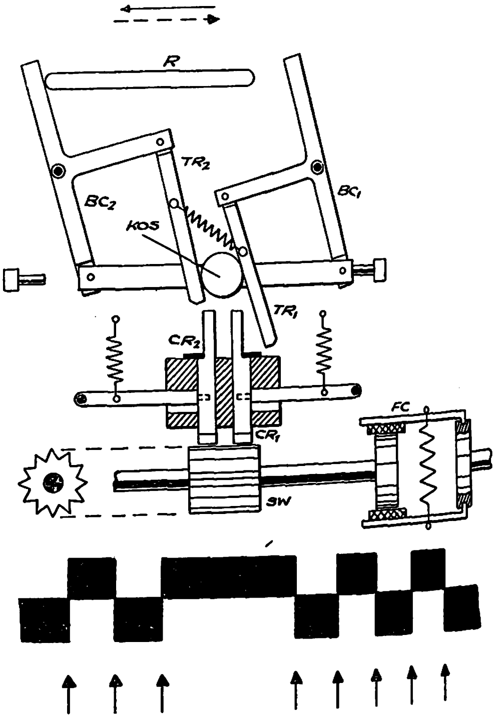

FIG. 28.—Creed's correction mechanism.

arrangement shown in Fig. 25 was introduced on the Algiers cables in 1910 by Picard. He interposed a relay between the correcting segment and the correcting magnet. As the relay has constant sensitiveness and little or no remanence, the action point remains constant. Furthermore, correction is always effected with impulses of constant duration, viz. the full length of the segment to which the correcting magnet is connected.

Correcting Mechanisms.—Fig. 26 is an early form of Baudot's epicyclic corrector. The brushes B are attached to a frame-like carrier BC free on the constantly driven shaft S, but locked to it by the epicyclic train consisting of the wheel LW held by the jockey roller JR_1 and the gears G_2 and G_1. On an extension of the shaft carrying wheels LW and G_2 is a star wheel SW. Two pins P_2 and P_1 can be thrust into the path of SW by means of two correcting magnets (not shown) and either unlock the train pushing BC and the brushes onwards in the direction of rotation, or momentarily uncouple them from shaft S. Thus the brush system can be retarded or advanced, according to which correcting magnet is operated. As previously stated, the general practice is now to run the controlled distributor slightly faster than the controller and adjust backwards when a certain phase difference has accumulated. One of the pins and its operating magnet is therefore suppressed. Correction can only be effected at one part of the revolution, and if it is to be effected from the signals the correction condition must be stored until the moment for operation is a suitable one.

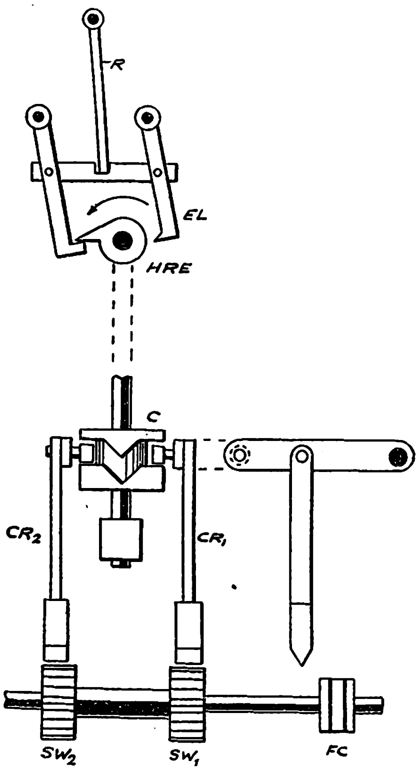

FIG. 29.—Creed-Willson correcting mechanism.

Under these conditions, it is not possible to allow for correction to be effected more than once or at most twice per revolution. Speed differences must therefore be small and the gear ratio G_1/G_2 high. This defect is overcome by Rothermel's construction, shown in Fig. 27. Here the gear train, locked at RW by means not shown, is controlled by a pawl P operated by a correcting magnet CM which is carried round with the mechanism, being mounted on the disc D, and the ends of its windings are carried to slip rings not shown. Correction can take place at any time during a revolution and more than once in the same revolution.

Fig. 28 is a diagrammatic representation of the well-known Creed correcting mechanism. It consists of two bell-cranks BC_1 and BC_2 pivoted at their mid-points to the machine frame. They are alternately rocked by a reciprocator R—controlled by the line signals—so as to move from right to left. The bell-cranks are pivoted at their lower end to a horizontal bar provided with a knock-off stud KOS. The horizontal portions of the bell-cranks are provided with trip rods TR_1 and TR_2. The motor is coupled to the main shaft of the mechanism through a friction clutch FS, and on the secondary shaft is a star wheel SW. Adjacent to SW are two corrector rods CR_1 and CR_2, which are thrust into the teeth of the star wheel each time the reciprocator R reverses its position by the trip rods under control of the bell-cranks. The corrective effects are transient as the knock-off stud KOS pushes the trip rods off the tops of the corrector rod at an early part of each cycle of operations. Correction is effected each time the line current changes sign, as shown in the lower part of the diagram. This mechanism corrects either backwards or forwards, as may be required at any instant, and it is only necessary to adjust and maintain the motor speed constant for practical synchronism to be maintained. Fig. 29 is the Creed-Willson corrector mechanism, which represents a considerable simplification. R is reciprocated by the

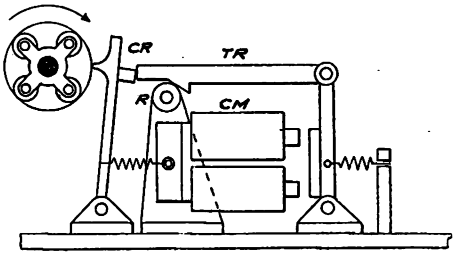

FIG. 30.—Wood's correcting mechanism.

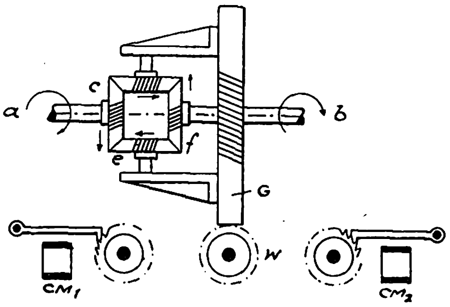

FIG. 31.—American epicyclic corrector.

line signals, and by means of the two escapement levers EL allows a shaft carrying the cam C to make a half-revolution each time R is reversed by the agency of EL and HRE. Cam C drives forward the corrector rods CR_1 and CR_2, which engage star wheels SW_1 and SW_2, thus effecting phase adjustment of a second shaft yieldingly driven by clutch FC.

Fig. 30 is Wood's corrector mechanism. The shaft is timed to make 1 revolution for 4 signal elements. The corrector rod CR is arranged to advance or retard the shaft according to requirements, the pointed tongue of corrector rod CR meeting the surface of the rollers to effect the phase adjustment. The trip rod TR has a cam surface on its under side which, as TR is pushed forward by the correcting magnet, raises it by means of the roller R and releases CR.

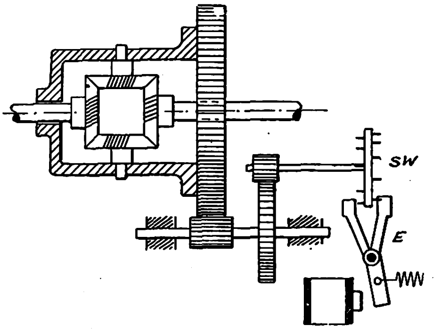

Fig. 32.—Foll and Muirhead's correcting gear.

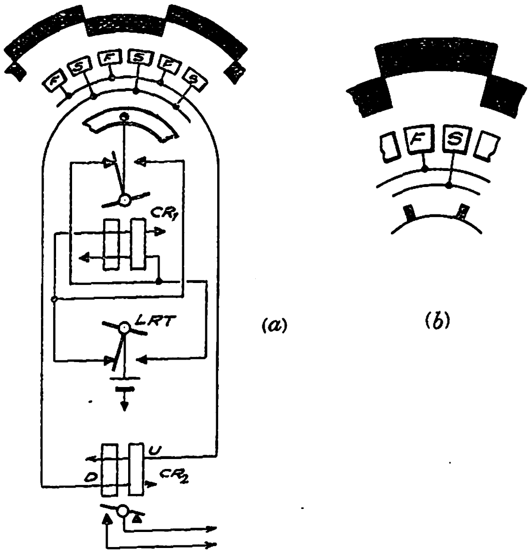

(a) (b)

Fig. 33.—Generation of correction pulses from signals.

Fig. 31 is the mechanical corrector used on the New York–Emden loaded cable multiplex circuit. The driving shaft " a " is coupled to the driven shaft " b " by means of the differential gear. The gear is supported on the two shafts and by brackets carried on the large gear-wheel G. The latter is loose on " b " but is locked against rotation by the worm-wheel W. The shaft to which the worm-wheel is keyed can be rotated by either of two correcting magnets, CM_1 and CM_2, by which the shaft " b " is set back or advanced by a small amount each time a correcting magnet is operated.

Fig. 32 is an epicyclic corrector due to Messrs. Foll and Muirhead, in which the correcting magnet controls an escapement E by which the scape-wheel SW is intermittently released. No phase change between the two shafts takes place normally, the differential gear being locked by SW. The correcting magnet has only to do the work of releasing the train, the work necessary to vary the phase being thrown on the motor.

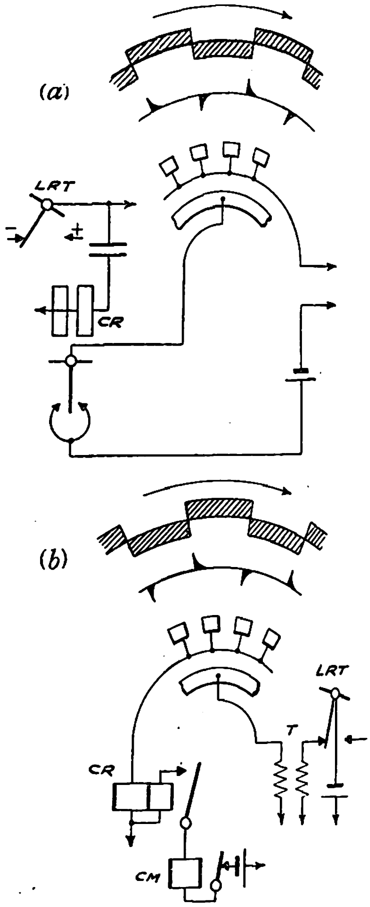

Fig. 34.—Generation of correction pulses from line signals.

Generation of Correction Impulses.

A variety of methods of generating correcting impulses are in existence and are employed in one form or another. A difference of phase is the primary requisite and it is becoming more and more the general practice to rely on the signals themselves to make the necessary change before the cumulative phase difference has reached the operating limit. In all systems of machine telegraphy, e.m.f. or current changes occur at certain definite times, which are separated by definite integral multiples of a time element—the elementary signal.

Fig. 33(a) is a typical example of the arrangements necessary for correction generation from the signals. With correct phase relationship, the changes in sign of the line current will occur exactly in the space between the slow and fast segments S and F. The line relay tongue LRT vibrates in accordance with the incoming signal and CR_1 vibrates similarly, but with a slight lag, under control of LRT. At the instant of change of current the line relay and relay CR_1 will have their armatures on opposite contacts, during which short interval a current can pass from earthed battery, left-hand contact, say, of LRT, right-hand contact of CR_1, solid ring of distributor, via the brushes (not shown) to either the slow or fast segment, depending upon the phase of the distributor brush with respect to these at the moment LRT has been reversed. The second correcting relay CR_2 will therefore be operated either to close the circuit of a correcting magnet or, if correction has been taking place and the phase difference has been annulled and carried slightly over in the other direction, so to operate CR_2 as to open the circuit to the correcting magnet. The circuit described for setting relay CR_2 is only momentarily established since CR_1 ultimately moves in obedience to the current from LRT, but once the correcting condition of CR_2 is set up it is not altered until the correction is effected and the phase difference changed in sign. The revolving brushes will therefore have a periodical phase difference which will alternately be above and below that of the controlling brushes at the other end of the line. Fig. 33(b) shows how the correction pulses fall if the phase is behind or in front at the corrected station. In this method of correction, the necessary conditions are set up regardless of whether the change in sign of the line signal is from positive to negative or the reverse. The corrected speed is arranged to be slightly faster than that at the correcting end of the line.

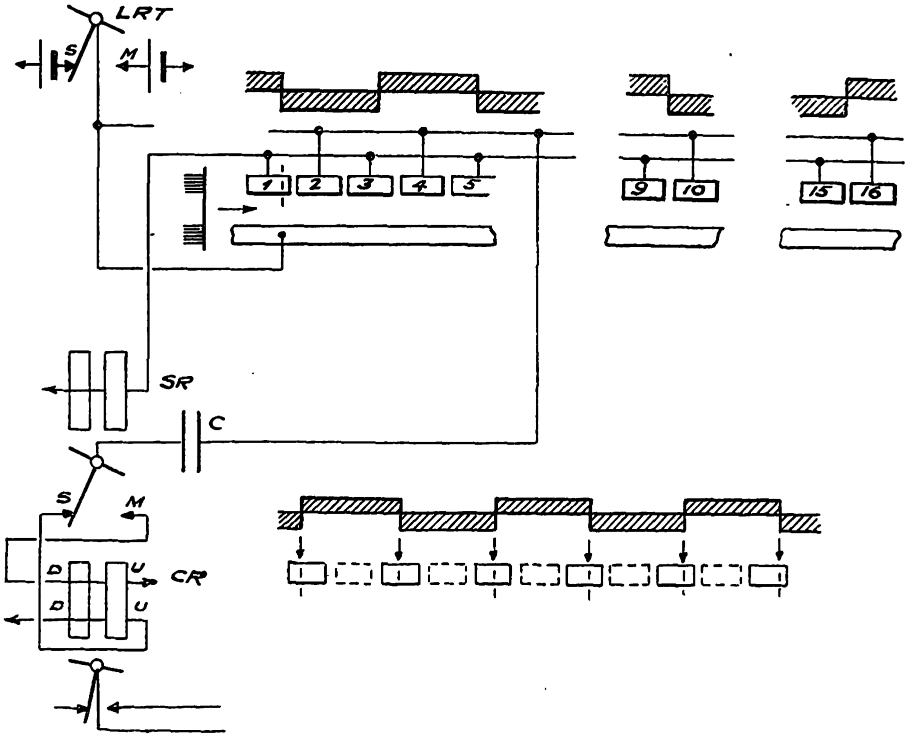

FIG. 35.—Picard's system of correction from signals.

Fig. 34(a) is a variation. The line relay tongue controls the receiver electromagnets (not shown), but, in addition, operates a relay CR through a condenser. The relay CR is of the central-zero type and is deflected to its right-hand or left-hand contact in accordance with the sign of the transient condenser current. Only "slow" segments are provided and the distributor is arranged to run slow with respect to that at the other terminal of the line. When a certain phase difference has accumulated, the condenser pulses occur when the correcting relay is on one of its contacts, while the correcting circuit from the tongue of CR is closed via the solid ring of the distributor and the right-hand extremity of any one of the correcting segments. The effect of correction is to speed up the distributor until, when the correcting pulses operate CR_1, the distributor brush is clear of the right-hand end of the correcting segments, and the corrector circuit is broken down. The distributor again falls behind until the correcting condition is again set up, and so on.

Fig. 34(b) differs from Fig. 34(a) in the generation of the transient correcting pulse and also by reason of the fact that only "fast" segments are provided. As the line relay tongue reverses, it makes and breaks the primary circuit of a transformer T. From the secondary of T, pulses pass via the distributor to a non-polarized correcting relay CR. This operates and locks itself up through a holding winding from earthed battery, interrupter springs on CM and armature of CR. By this arrangement the continued operation of CR is assured until the correcting magnet is fully actuated. The distributor in this case runs slightly fast.

Picard's Correction from the Signals.—Fig. 35 explains the correction method due to Picard, which may be said to be the basis of all modern methods. When synchronism exists, reversal of sign takes place when the brushes are very near the end of the odd-numbered correcting segments. The pulse of current is still long enough to operate the switching relay SR, which thus follows the motion of LRT. If the pulse is negative, relay SR spaces. This puts the lower winding of the correcting relay CR in connection with the condenser C, and when the brush passes over the succeeding even-numbered segment the condenser is negatively charged and the charging current puts the relay CR to spacing. Nothing is changed.

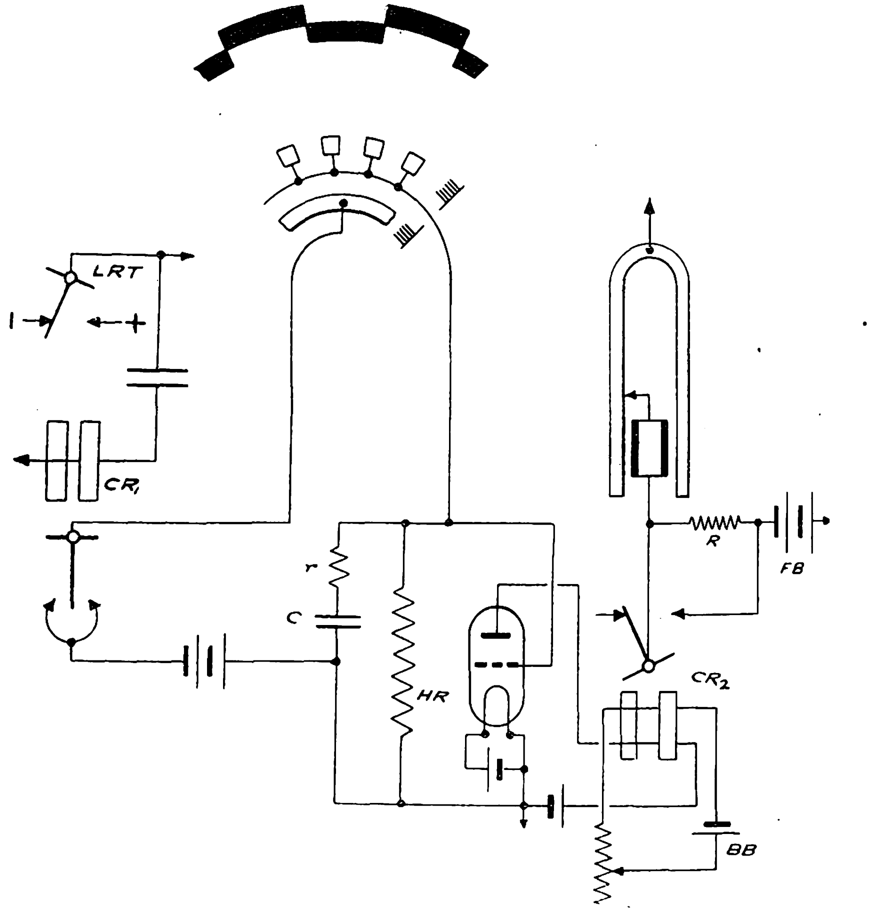

FIG. 36.—Western Electric Co.'s method of correction using a thermionic valve.

If a positive signal follows when the brush arrives at the end of the third contact, so that the pulse is still sufficient to operate SR, this marks but the correcting relay will still space because although the pulse is opposite in sign to the previous one it passes through the upper winding of CR in the opposite direction.

When the distributor, which is set to run slightly fast, has gained sufficiently, the moment of reversal will occur between the odd- and even-numbered segments or even on the commencement of the even-numbered one. Relay SR will no longer reverse with LRT but will remain where it was last placed. If the previous signal pulse was positive, the tongue of SR will be on its marking stop and the negative condenser-charging current will operate CR to the marking position, where it operates the correcting magnet (not shown).

In the Picard arrangement, the Baudot epicyclic corrector was employed. As this can be operated only at one part of a revolution, the correction is stored by CR until the brushes close, at a suitable moment, the circuit of the correcting magnet. The lower part of the diagram shows the creeping forward of the "action point" as the distributor gains in phase. At the right hand two opposite changes of sign are shown, from which it will be seen that the correction effect is generated in either case, provided the necessary phase difference has arisen.

The arrangement of Fig. 36, designed by the Western Electric Co., is applicable where extremely close synchronism is required. Correcting relay CR_1 is of the 3-position type, and, at each change of sign in the line current, is momentarily placed on one or other of its contacts. The negative pole of the battery connected to these contacts is applied via the solid ring and correcting segments of the distributor and to the high resistance HR and resistance "r" and capacity C in parallel. Condenser C is charged and negative potential is applied to the grid of the thermionic valve, causing a reduction in the plate current circulating round one winding of a second correcting relay CR_2. Current from the biasing battery BB is adjusted by a series resistance, so that with normal plate current relay CR_2 is maintained in its operative position, where it short-circuits the resistance R in series with the fork-driving battery FB, causing the fork to run slowly. When the current in the plate circuit is reduced by receipt of a correction pulse, as previously explained, the armature falls back to its unoperated position, shown in the diagram, due to the current in the output circuit of the valve being reduced by the application of a negative potential on the input circuit, and the biasing current from BB overcoming this. Resistance R is now in circuit with the fork-driving magnet and the reduced current results in the fork amplitude decreasing and the fork frequency rising, thus hurrying up the motor. The fork continues to run fast until the charge on condenser C has leaked off through resistance HR. This arrangement differs from other synchronizing systems in that the accuracy of correction is not dependent upon the time required for a current to reach an operating value in an electromagnet, but is determined solely by the time required to build up a charge on the condenser C. Thus a very small instant of time is required to register the correcting condition, and synchronism is held within extremely narrow limits.

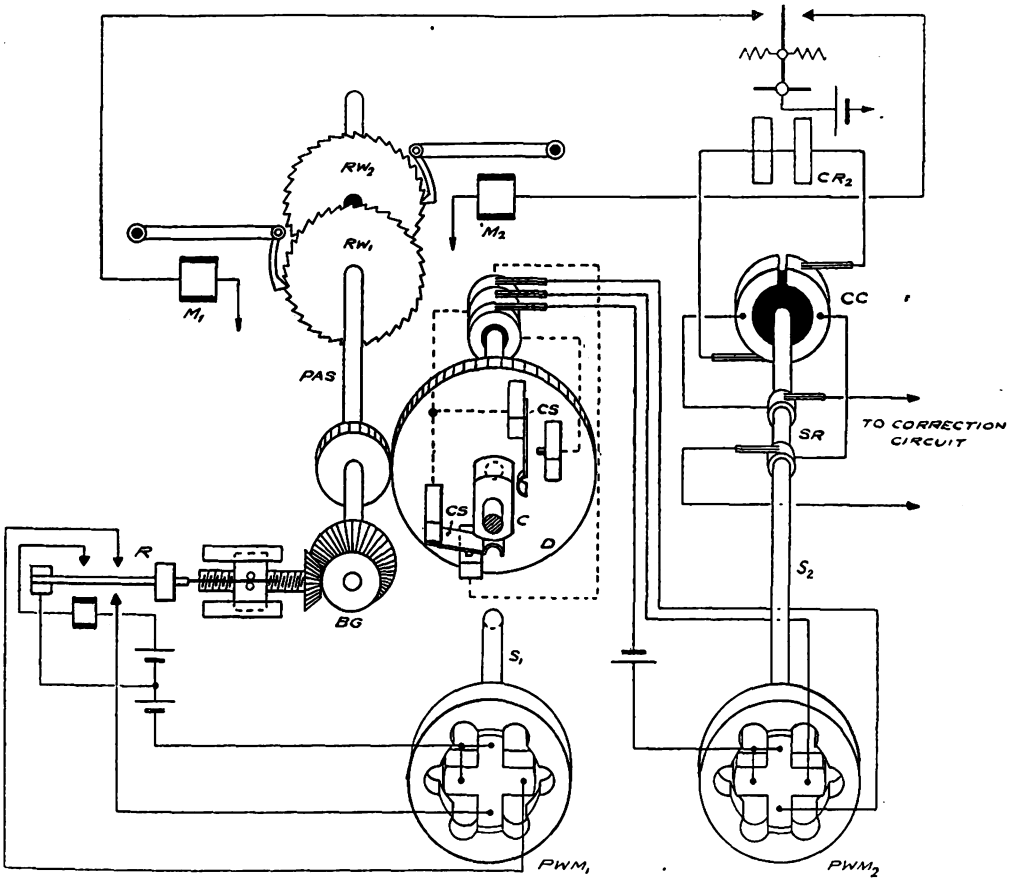

FIG. 37.—Pernot's speed and phase control of phonic-wheel motors.

Pernot's Method.—Fig. 37 represents a system of correction invented by F. E. Pernot, in which the integral of all phase corrections is applied in such a manner as to vary the speed and thus make fewer phase corrections necessary. It is designed to secure synchronism on a circuit operated by cable code morse.

R is a reed operating a phonic-wheel motor PWM_1. This motor rotates a cam C revolving in the path of two contact springs CS adapted alternately to deflect these against fixed contacts. The contacts and springs are fixed to a toothed disc D loose on shaft S_1, the springs being connected together and to a slip-ring on shaft S_1. The contacts are also connected to two other slip-rings, and the regular rotation of cam C furnishes driving pulses to a second phonic motor PWM_2. The vibrating end of reed R carries a spring which passes between two pins on a slide capable of to-and-fro motion. When the pins are near the end of the reed R the stiffness of the latter is increased and also the rate of vibration, and vice versa. Adjustment of the slide with the constraining pins to or from the reed constitutes a vernier adjustment, the weight on the reed furnishing the coarse adjustment to the approximately correct rate of vibration. The vernier adjustment is effected by means of shaft PAS and the bevel gear BG, which is operated in one direction or the other by means of the two ratchet wheels RW_1 and RW_2 having oppositely disposed teeth and actuated by electrically controlled pawl-and-ratchet mechanism. Two electromagnets M_1 and M_2 step the ratchet wheels on one tooth each time they receive a current pulse.

The shaft PAS not only varies the adjustment of the reed R, but, by means of a pinion meshing with the teeth on the periphery of the disc D, rotates this slightly.

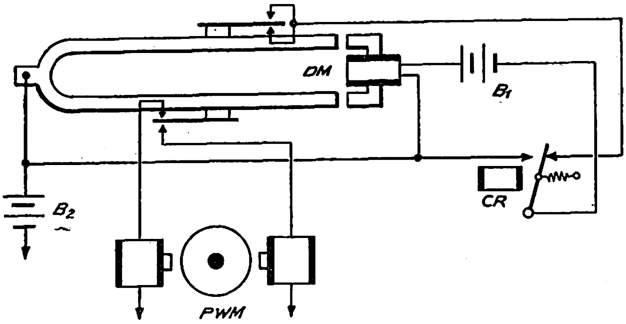

Fig. 38.—Muirhead's speed and phase control of a tuning fork by line signals.

The effect of this operation of D is that the relationship of the contact springs and contacts on D is altered with respect to the cam C, and the phase of the driving pulses furnished to the second phonic motor PWM_2 is altered thereby. The two motors make one rotation for a dot-and-space signal element, and motor PWM_2 drives the cam shaft of a receiving perforator or retransmitter of the regenerative type. By suitable means, transient correction impulses are generated at the beginning of each signal element or block signal coming over the line. These impulses are passed to the second correcting relay CR_2 via slip-rings SR, the two sectors of the correcting commutator CC and the two brushes resting on this and connected to the windings of CR_2. If the phase is exactly right, the circuit to CR_2 is not completed, since the two brushes of CC will rest on diametrically opposite insulated sections between the two segments, and no correction takes place. If PWM_2 leads or lags, CC acts as a reversing switch and CR_2 is actuated in the appropriate direction to operate M_1 and M_2 and vary the speed of reed R, while also effecting the phase adjustment previously described. As previously stated, if phase error persists in one direction the gradual minute adjustments to the rate of vibration of the reed effect a permanent change in speed, and the closeness with which the synchronism is maintained is far greater than in any of the systems previously described. Such refinement is not necessary for land lines, but on long cables and where two or more cables are interlinked it is essential; the additional distortion which would otherwise be introduced by relatively coarse phase errors makes such interlinking impossible.

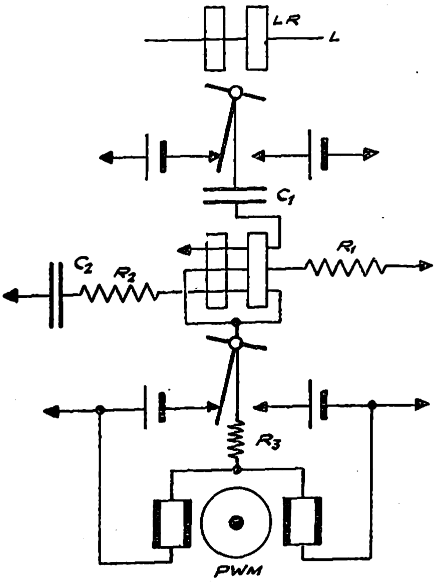

Fig. 39.—Bille's control of phonic-wheel motor by Gulstad relay.

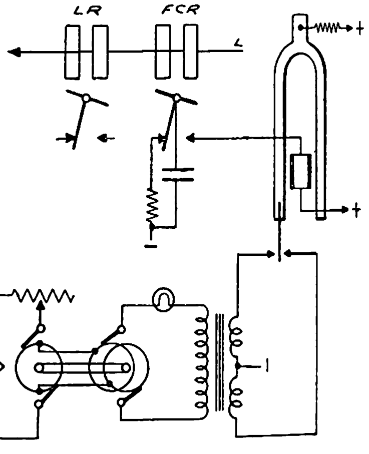

Fig. 40.—Angel's control of d.c. motor by line-signal control of a tuning fork.

Control of Tuning-Fork Speed and Phase by Line Signals.

The speed and phase of a tuning fork may be controlled in two or three ways by means of the line signals.

It is possible:—

To modify the speed of the fork by correction impulses generated by the signals.

To cause the line signals to exercise an interference effect in the fork driving circuit.

Positively to drive the fork by driving pulses generated from the line signals.

An example of the first is furnished by Fig. 36, while a requisite condition for the second and third is that the fork frequency should bear a definite relation to the signalling frequency.

Heurtley and Foll's Method.—Fig. 38 is an example of the second method of fork speed and phase control and is due to Messrs. Heurtley and Foll. In this arrangement the driving magnet DM exercises the necessary control. The circuit of this magnet is taken through the back and front contacts of a correcting relay CR, which is operated each time a line-signal element is received.

If the fork is out of phase with the incoming signals, the driving impulse is given at the instant when the fork

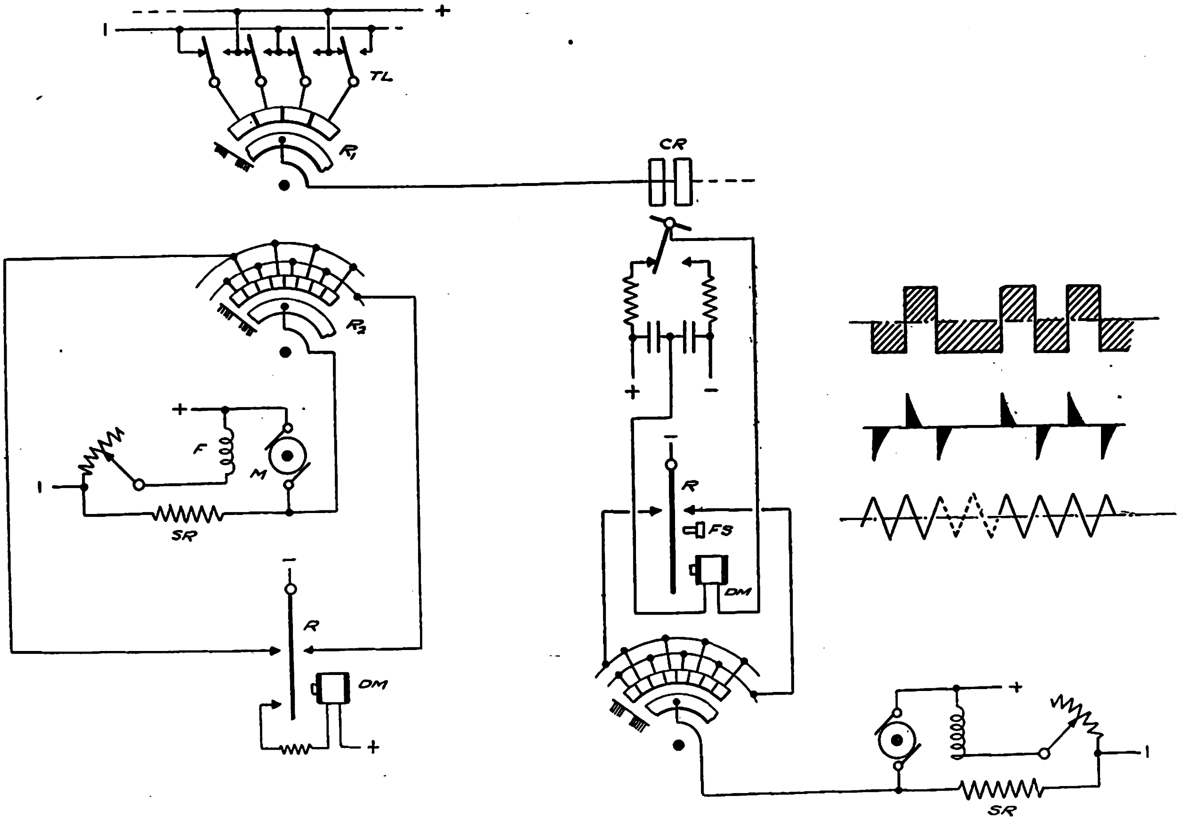

FIG. 41.—Potts's control of speed and phase of d.c. motors by synchronous reeds.

would normally be free and the fork is forced into the correct phase relationship. The driving fork does not cease to vibrate when the line signals stop, the driving circuit being closed at the back contact of CR and the usual spring contact on one tine and its adjacent fixed contacts. Under these conditions it vibrates at the speed for which it is adjusted, the line signals correcting phase when required. If no signals are passing, then, before commencing transmission, it is only necessary to send a few reversals to bring the fork into phase.

Bille's Method.—Fig. 39, due to the late Harald Bille, employs the well-known Gulstad relay as the timed vibrator. It vibrates by means of its local windings, and the rate of vibration is adjusted by resistances R_1, R_2, and condenser C_2. In addition its vibrating tongue pulses the magnets of the phonic-wheel motor PWM. Any slight difference between the rate of vibration of the relay and the rate of reversals from the distant transmitter is compensated by the control exercised by the signals on the line winding of the relay which is pulled into phase each time the line relay reverses its armature. This control is exercised through a condenser G, so that only transient correcting pulses are generated. If the condenser were not provided, a long signal pulse would temporarily stop the vibration and PWM would cease to rotate.

Angel's Method.—Fig. 40 is an arrangement of H. Angel in which a fork, timed to vibrate at the rate of transmission of dot-signal cycles, is driven by a fork control relay FCR in series with the line relay and moving similarly to this in response to line signals. The fork is used to control the speed of a d.c. motor in the manner described with reference to Fig. 6. If a long signal pulse is received, it only exerts an effect at the initial stage, and the fork continues to vibrate by its own persistence until a reversal in the line-signal current takes place and generates a further driving pulse.

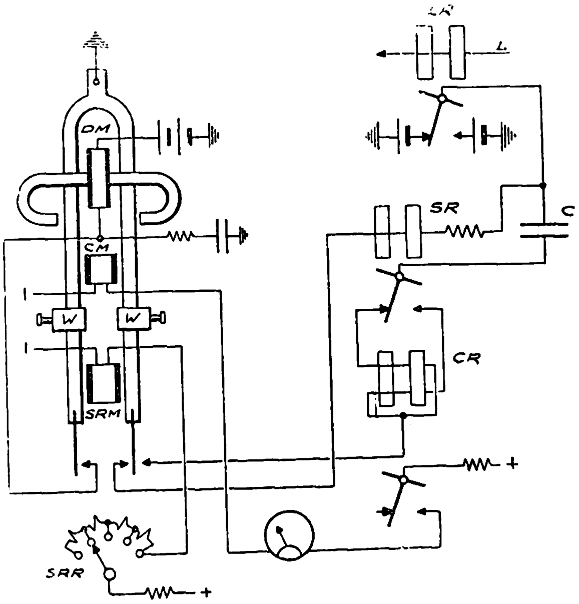

FIG. 42.—Connery's speed and phase control of a fork by line signals.

Potts's Method.—Fork or reed control of d.c. motors at both ends of the line may be effected by the arrangement detailed in Fig. 41 and due to L. M. Potts. When no signalling is taking place, the transmitter levers normally send out alternative negative and positive pulses. The d.c. motor at the sending end is kept to a certain mean speed by the accurately timed reed R, which acts through the speed control segments of R_2 in the manner described with reference to Fig. 7. At the receiving end a similar motor is controlled by a vibrating reed R driven by the signal pulses in the manner explained in connection with Figs. 39 and 40. The operation of the controlled reed at the receiving station is clear from the inset diagram at the right.

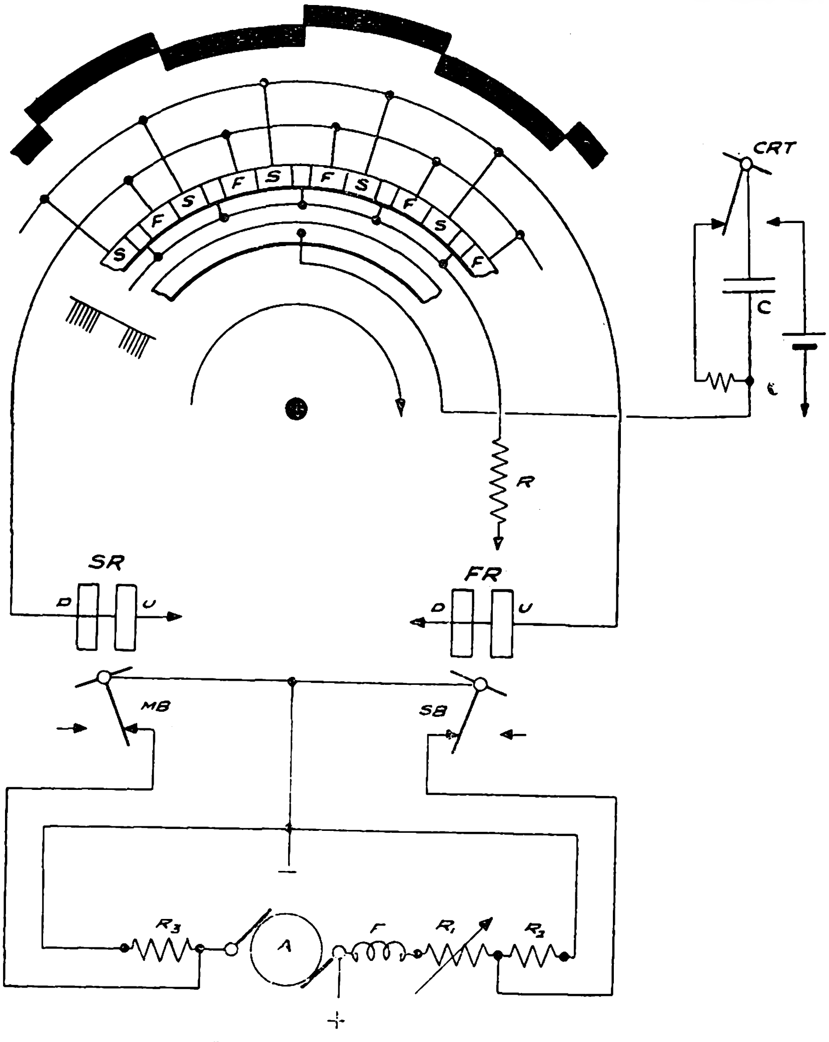

FIG. 43.—Speed and phase control of d.c. motor by line signals.

Connery's Method.—A fork may be kept vibrating at constant speed by correction pulses generated from the line signals. Such an arrangement, due to A. F. Connery, is illustrated by Fig 42. The fork is brought to approximately correct rate of vibration by means of the usual sliding weights WW. A speed-regulating magnet SRM carries a current adjusted by a speed-regulating resistance SRR and constitutes a vernier adjustment, SRM varying the stiffness of the tines. The driving magnet DM is operated in the usual way and a correcting magnet CM is operated by a relay chain formed of a switching relay SR and correcting relay CR. Two contacts adjacent to a contact spring on the right-hand tine of the fork, together with the relay chain, form a correcting arrangement identical with that of Picard (Fig. 35), the two fork contacts corresponding to the fast and slow segments of Picard. The rate of vibration of the fork is so adjusted that with no current flowing through the corrector magnet CM slightly less than one cycle of vibration occurs for each unit length of line signal. When a current is passed through the correcting magnet CM the fork speed is increased so that it vibrates at slightly more than one cycle per unit time. When the fork gets out of phase the correcting condition is set up and CM operates.

Forward and Backward Correction of D.C. Motor.—If both forward and backward correction are used, then, with suitable control, synchronism can be obtained with motors having no inherent time-keeping properties, i.e. d.c. motors. Fig. 43 represents such an arrangement. The usual slow and fast segments are provided, separated by a third, shorter segment connected through a resistance R to earth. The three groups of segments are multipled together within the group, the fast segments being connected to a slow relay SR and the slow segments to a fast relay FR. These relays have spacing and marking biases as indicated. CRT is the tongue of a correcting relay operating with the line-signal relay—not shown—in response to the line signals. In the normal position of CRT a condenser C is short-circuited through a resistance R. In the operative position of CRT a charging circuit is prepared for C from earth, battery, right-hand contact of CRT, condenser C, and solid ring of correction segments. If the distributor brushes are in phase, the condenser charges up through the small segment between the slow and fast segments and the resistance R. If the distributor brushes lag, the charging pulse passes through the fast relay, which operates momentarily and removes a short-circuit from a field resistance R_2, thus accelerating the motor. If the brushes are in advance, the condenser-charging pulse is effected through the slow relay and this inserts a resistance R_3 in the armature circuit, slowing the motor down. The correcting effects are only transient; both relays return to their normal positions, as shown, due to the bias. Correction is only effected on a change of line signal from negative to positive. With suitable speed adjustments, the brush arm floats round the correct phase position, the phase varying slightly in front of and behind the correct position.

Salmon's Method.—An extremely simple and effective method of speed and phase control of a d.c. motor by the line signals, due to R. D. Salmon, is diagrammatically indicated in Fig. 44. On the shaft of the motor DCM is a disc D on which are mounted two governors consisting of pivoted, spring-controlled weighted arms. One is adjusted to control the motor at a certain speed S_1; CRT is a 2-position switch which is operated when the shaft acquires a phase difference above or below that of the distant shaft with which synchronism is to be effected. The position of CRT is dependent upon the detection of phase difference by means of the incoming line signals. In the position shown in the diagram, governor S_2 is operative, S_1 being disconnected at CRT. In course of time the phase of the motor shaft will have advanced so far that the position of CRT will reverse. Immediately this occurs the circuit of S_1 is completed and the shunt field resistance SR is short-circuited, thus slowing the motor down. This will proceed until the phase lags sufficiently again to occupy the position shown in the diagram. S_1 no longer has any effect and the motor speeds up until S_2 again takes charge. Thus the phase of the shaft is kept floating about the correct position and this variation can be made as small as we please by suitable choice of the two control speeds S_1 and S_2. The spring tension is such that if it were possible for the pivoted arms to be at the geometrical centre of the disc it would be zero. By previously calibrating the springs in the factory it is possible to apply the governor to any d.c. motor and rely on obtaining the speed range equivalent to the difference between the speeds of S_2 and S_1.

Start-Stop Synchronism.

A relatively coarse synchronizing method is that applied to start-stop printing telegraph systems (Fig. 45). Here the contact brush-arms of the distributors start and stop for each letter signal transmitted and received. This allows of about 7 per cent difference of speed between the motors at the two ends of the line, since the phase difference is not allowed to accumulate. The motors M are controlled, as regards speed, by means of a centrifugal governor G controlling a contact arm CA adapted to short-circuit a shunt regulating resistance SRR. The exact speed at which the governor exercises control is fixed by a speed-adjusting screw SAS. The motor speed is adjusted to a suitable value by the aid of a stroboscopic disc SD viewed through a calibrated fork CF mechanically operated by a push-button PB and hammer H.

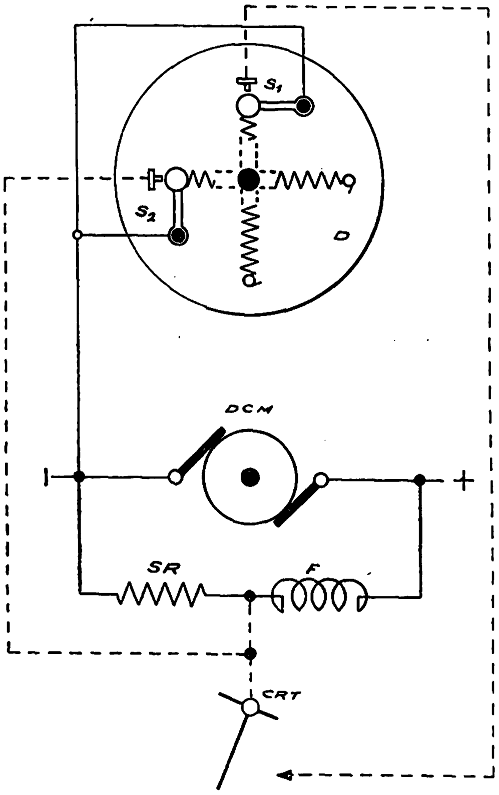

FIG. 44.—Salmon's governor method of speed and phase control of a d.c. motor.

The distributor brush-arms are yieldingly driven and held against revolution by release arms such as RA. At the sending end RA is released every time a character key lever CKL is depressed, this being effected by a universal bar UB linked to the release arm RA. At the receiving end the release arm is electromagnetically controlled by a start magnet SM, which is operated by a start pulse prefixed to the 5 signal pulses and sent out as soon as the sending distributor brush-arm commences its movement. The cycle of operations is set out in the inset diagram.

Start-stop synchronism is easy to obtain and maintain, the only adjustment necessary being intermittent checking of the motor speed.

Local Synchronism.

Local synchronism is the synchronism required between printer and distributor units of a multiplex system. Where the printers run continuously, as in the Baudot system, they may be run slightly faster than the distributor unit and periodically checked, or they may be provided with synchronous motors driven by reversals generated at the distributor.

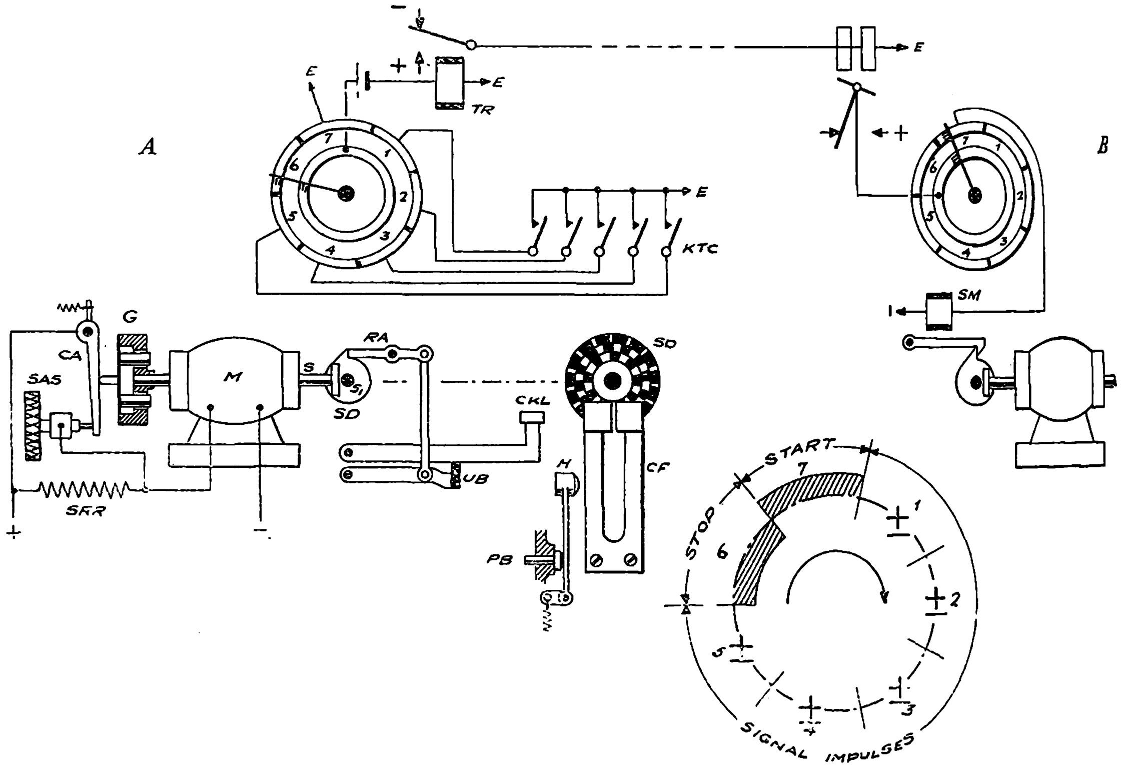

FIG. 45.—Start-stop synchronism.

In Fig. 46 S_1 is the distributor shaft driven by a motor (not shown), and S_2 is the printer shaft driven by the motor M. A cam C on S_2 partially closes a circuit to a magnet CM, the circuit being completed by a contact on the distributor, the solid ring, the brushes, and an earthed battery. The closing of the cam contacts and the distributor contacts coincides more or less frequently, depending upon the difference in speed of the two shafts, and CM operates, disconnecting the power supply from the mains and short-circuiting the motor, which then runs as a generator and slows down momentarily, thus annulling the phase difference which has accumulated. Some form of governor is fitted to the motor M to keep the speed of S_2 roughly constant.

In Fig. 47 the printer unit is driven by a synchronous motor from a commutator on the distributor. The method of operation is obvious. The synchronous motor is not self-starting but comes into step after two or three revolutions by hand. This system has the advantage that there is no governor to adjust on the printer unit, while the phasing of the printer with respect to the distributor is automatically secured. This is also true of Fig. 46, the adjustment of cam C on shaft S_2 effecting automatic phasing.

General Principles of Synchronizing Schemes.

Practically all of the arrangements previously described will be found to consist of:—

(i) A variable phase-detecting means operating by the rotating shaft to be controlled.
(ii) A device responsive to the received signals, and
(iii) A speed- or phase-variation means by which correction is effected.

The process of maintaining synchronism is as follows:—A continuous comparison is instituted between (i) and (ii), (ii) being identical in phase with the controlling end of the line, and the positive or negative divergence is used to operate (iii).

Speed and Phase Indicators.

Fork-speed Adjustment.—In Fig. 48 the fork is adjusted to vibrate at a rate which will drive the phonic motor at the desired speed. With the switch S thrown into the reverse position to that shown in the diagram the solid ring of SDF connected to positive battery makes alternate connection with two groups of segments which are in turn connected to the two pairs of motor magnets through S. When any segment is bridged to the solid ring by the brushes (not shown), one tooth of the motor is between the pole-pieces of one pair of magnets. The motor starts up and gradually accelerates. The drive is transferred from the distributor segments by placing S in the position shown in the diagram, and this moment is indicated by the flashing of the synchronizing lamp SL.

When the brush is on a segment connected to the lamp at the same instant that the fork-vibrating contact is touching its left-hand fixed contact, the lamp glows. As the motor gains speed, a series of flashes will be observed which become slower and of longer duration.

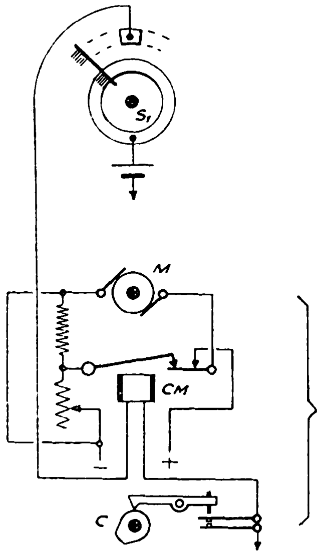

FIG. 46.—Local synchronism.

When the lamp appears to be on the point of glowing continuously, the switch is thrown and the fork then takes on the motor drive.

Fork-speed Adjustment to Speed of Distant Fork,—Fig. 49 shows an arrangement by which the fork speed at the distant station B can be adjusted by reference to that at A. At station A when the switch is thrown to the left, alternating current is sent out as indicated by the circular diagram L. When the switch at B is thrown to the dotted position, line relay LR controls a second electrically-biased relay, which responds to the alternating currents sent out from A and drives the phonic motor at the same speed as that at A. A stroboscopic disc SD is mounted on the shaft of the motor and can be viewed through a window formed by two small metal strips fastened to the tines of the fork. The fork at B is so adjusted that it is, say, slightly fast when the resistance in series with the driving magnet is in circuit.

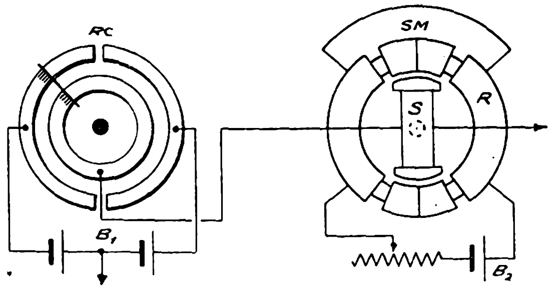

FIG. 47.—Local synchronism.

The adjustment of the distributor at B, so that it is in phase with that at A, is effected as follows: The switch at station A is turned to the right and the distributor then sends out positive current for half a revolution and negative for the other half, as indicated by the inset diagram marked R.

Switch S_2 at station B is now thrown to the right and divides the segments there into two groups of 10 each, as shown by the sketch R at the right-hand corner of the diagram. The two groups are each connected to separate windings of a polarized relay which, in its operated position, short-circuits the series driving magnet resistance, thus lowering the speed of the fork. If the distributor at B is in phase, no effect is produced on the fork speed-control relay, since its windings are so arranged that positive and negative pulses, if confined to the left- and right-hand groups of segments as at station A, only hold this relay to the inoperative or spacing position. If there is a phase displacement of B with respect to A, either the positive or negative pulse will run over from one group of segments to the other, and the fork speed-control relay will be operated. This will continue until the speed corrections applied to the fork give rise to exact coincidence of phase.

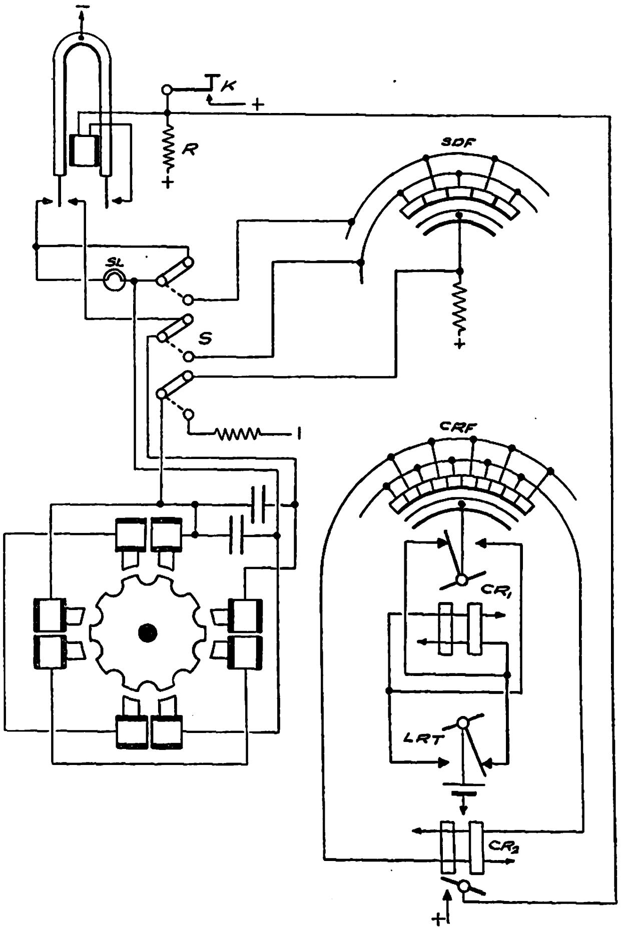

FIG. 48.—Fork-speed adjusting circuit.

When the speed and phase adjustments have been effected in the manner explained, other switches (not shown) connect up the apparatus at both ends of the line for traffic.

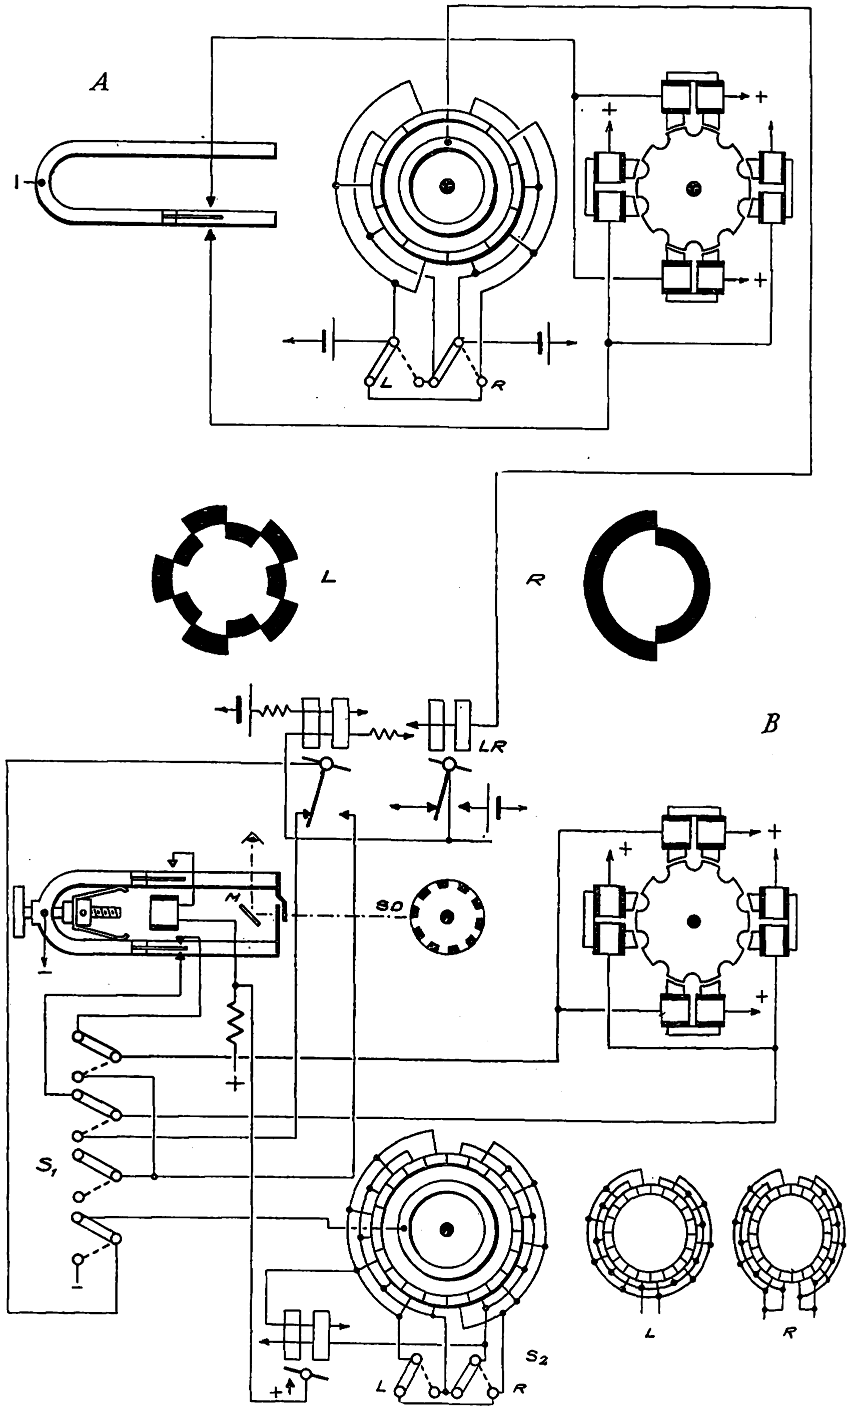

FIG. 49.—Speed and phase adjustment means between two stations.

Morkrum's Speed Indicator.—An ingenious and effective speed indicator by means of which a motor may be adjusted to the same speed as another distant motor is illustrated in Fig. 50. Alternating current received over the line operates the line relay tongue, the marking contact of which is connected to alternate segments of ring R_2 on the distributor. Ring R_1 is provided with two groups of segments connected to fast and slow lamps F and S. Each alternate segment is separated by short insulated segments 1, 2 . . . 5, and the two rings are bridged by brushes CB. The indications of the two lamps show the state of affairs, which is explained by the lower portion of the diagram, in which a black circle represents a lighted lamp and a blank circle that the lamp is out. The period at which an observation is taken is when both lamps are either extinguished or glowing.

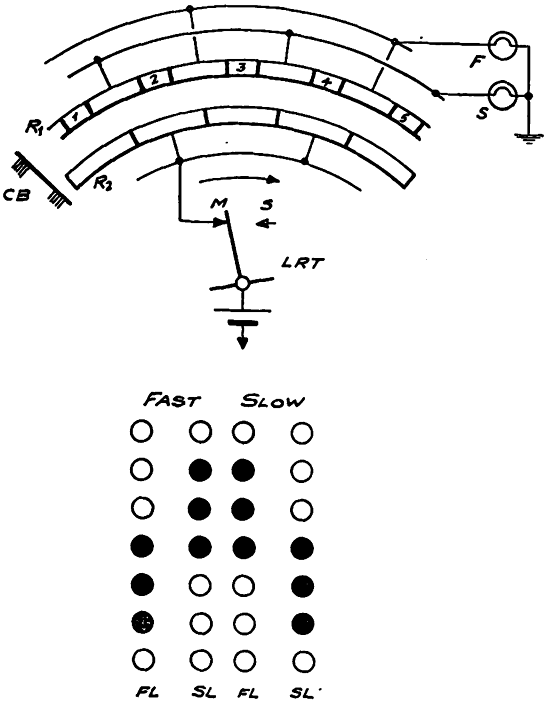

FIG. 50.—Morkrum's speed indicator.

The motor speed is seen to be fast when

After both lamps are extinguished, the fast lamp remains extinguished.

After both lamps are glowing, the fast lamp remains glowing.

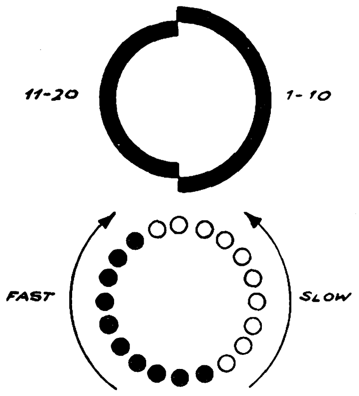

FIG. 51.—Speed and phase indicator.

If the motor speed is low, then

After both lamps are extinguished, the slow lamp remains so.

After both lamps are lit, the slow lamp remains lit.

If the difference of speed is considerable, the cycle between both lamps "out" to both lamps "in" is very short, but as the difference becomes smaller and smaller the cycle of change becomes longer and longer.

The author has had considerable experimental experience with this method and has found it easy to acquire the correct interpretation of the lamp indications, while

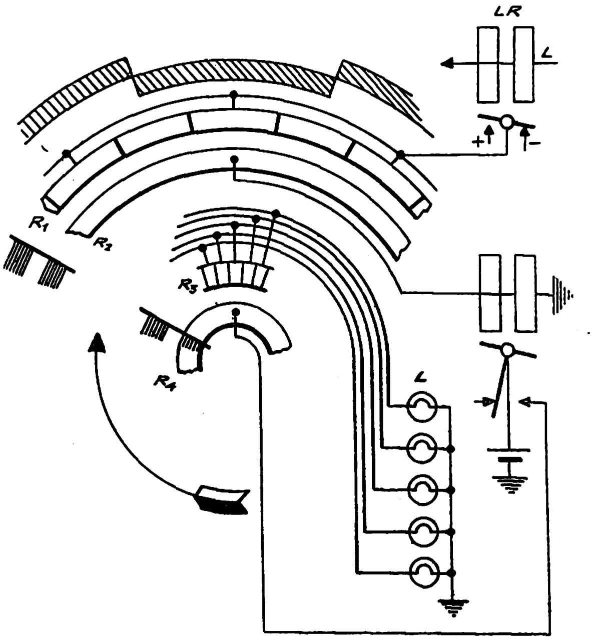

FIG. 52.—Western Union Co.'s speed and phase indicator.

it permits of a very close speed adjustment of the one motor to the speed of the other.

Simultaneous Speed and Phase Indicators.

If indicating lamps are connected to each of the receiving segments of a distributor and the distant distributor sends out positive current for one half-revolution and negative for the other half, then speed and phasing can be adjusted by observing the lamps. In Fig. 51 the distributors are provided with 20 segments which at one end are connected in two groups by a switch and arranged to send out positive and negative pulses, as shown in the upper part of the diagram. Any 10 of

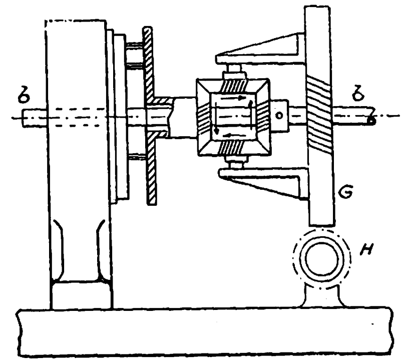

FIG. 53.—Phase adjustment of rotating brushes.

the 20 receiving lamps will be lit up, as seen in the lower diagram, and the actual 10 lighted indicate the instantaneous phase difference between the two distributors. The progression of the 10 lamps indicates whether the receiving distributor is fast or slow with respect to the distant one, and the rate of progression indicates the extent of the speed difference. When synchronism is attained, the lighted lamps remain stationary and then indicate the angle through which the receiving distributor has to be moved in order to come into phase with the distant distributor.

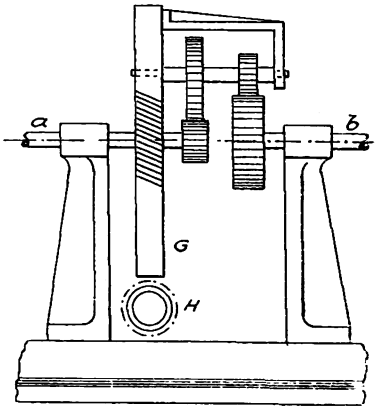

FIG. 54.—Phase adjustment of rotating brush shaft.

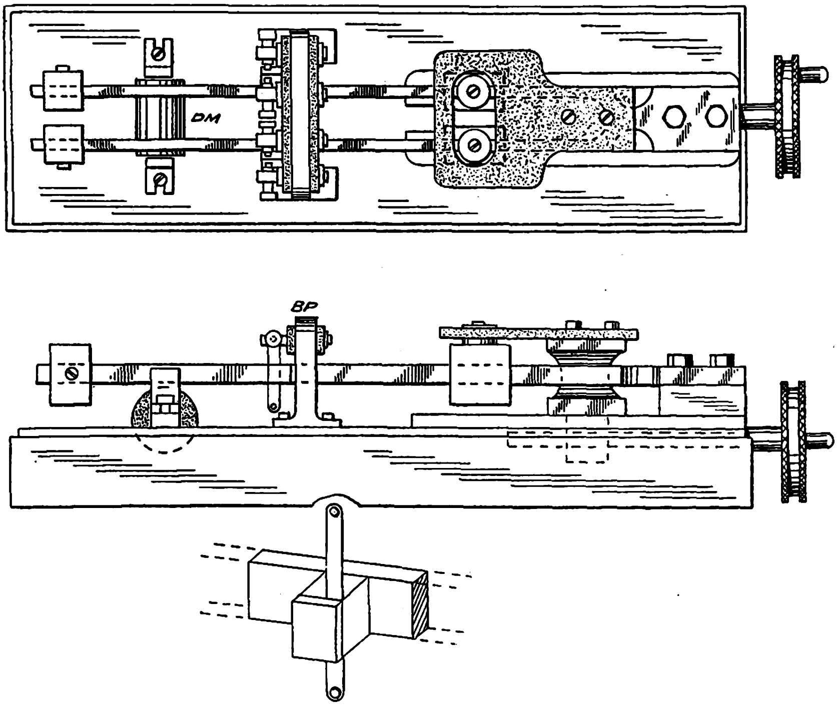

FIG. 56.—Muirhead's tuning fork.

Western Union Method.—Fig. 52 is an arrangement in use on the London–New York high-speed cable operated by the Western Union Co. Here 5 lamps are multipled to 5 segments of ring R_3 of a distributor. The direction in which these lamps light up (top to bottom, or vice versa) furnishes a speed indication and the lamps are afterwards used for adjustment of phase.

Phase Adjustment or Orientation.

It is the practice in America to secure orientation by adjusting the brushes while they are in motion. This is not only accurate and rapid but it obviates the mounting of segments on sliding sectors and the use of flexible trailing cables. Figs. 53 and 54 show two arrangements for effecting this which hardly require explanation.

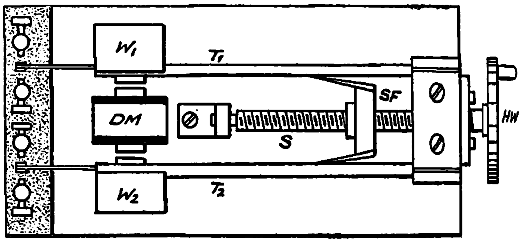

FIG. 55.—Carpentier's tuning fork.

Construction of Tuning Forks.

Carpentier's Fork.—Fig. 55 is a tuning fork constructed by Carpentier of Paris and adopted by the French Administration of Posts and Telegraphs for driving phonic-wheel distributors on Baudot multiplex installations. The two tines T_1 and T_2 are simple forged steel bars gripped at one end in a heavy cast-iron clamping block integral with the base. Sliding weights W_1 and W_2

effect a coarse adjustment of the rate of vibration, and a spring fork SF moved backwards and forwards by the hand-wheel HW constitutes a vernier means of setting. The two tines carry contact springs which butt against fixed contacts mounted on an insulated strip attached to the cast-iron base. The Baudot system runs at a standard speed of 3 revolutions per second and there is therefore no need for great refinement of method in the adjustment of the fork speed.

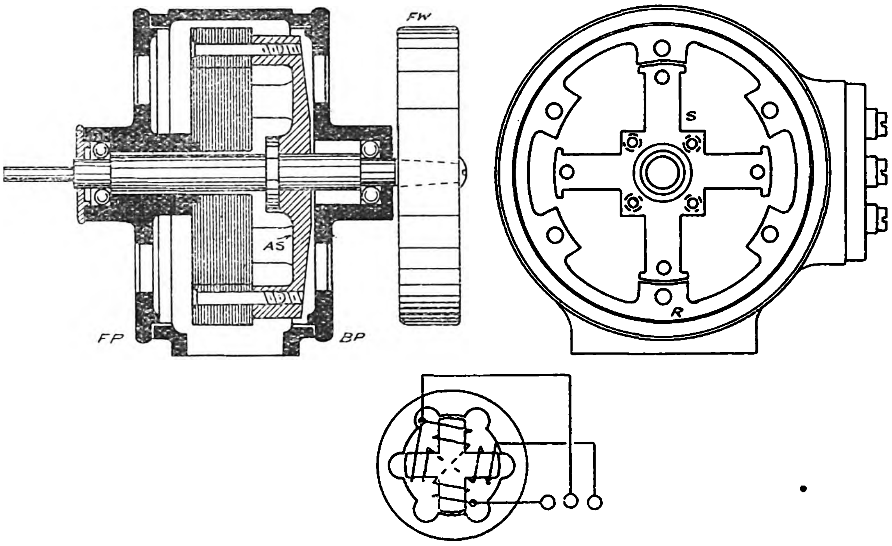

FIG. 57.—Eastern Telegraph Co.'s pattern phonic-wheel motor.

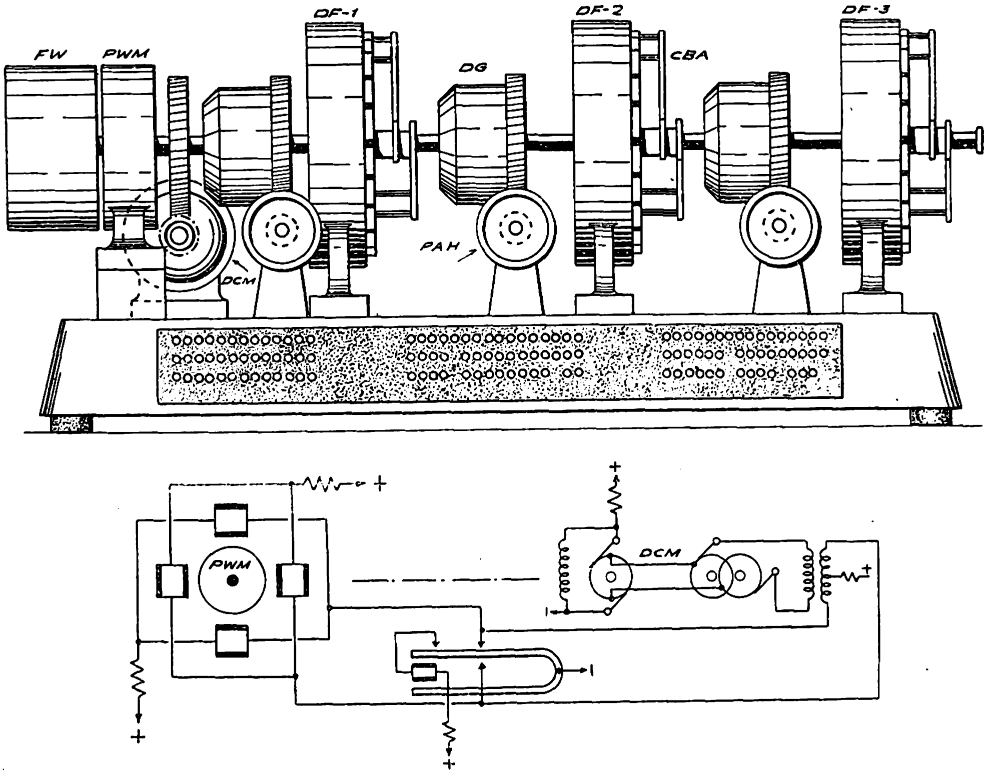

FIG. 58.—American pattern distributor.

Muirhead's Fork.—Fig. 56 shows a fork designed and constructed by Messrs. Muirhead and Co. The fork is, in this instance, a solid forging, the tang being bolted to a heavy block at the right-hand end of the base. Towards the free end a metal bridge piece BP straddles the two tines and carries two pairs of fixed contacts suitably insulated. The tines are each provided with a light leaf spring carrying platinum contacts, as is clearly shown in the second and third sketches. The free ends of the tines carry loading weights, a series of which are provided to give the fork a certain speed range. The vernier adjustment, which can be effected while the fork is running, consists of two sliding weights friction-tight on each tine, which weights can be moved to and fro by means of a bakelite shifting piece screwed to a sliding carriage controlled by a hand-wheel. Each weight has a ball-bearing roller pivoted to it, and these rollers enter a slot in the bakelite shifter. In this way the weights can be adjusted without interfering with the vibration of the fork, the rollers reducing the friction due to the contact of the bakelite shifter with them. The author has used two of these forks for over two years and has found them quite satisfactory.

Construction of Phonic-Wheel Synchronous Motors.

The usual construction of phonic-wheel motor is a laminated-iron toothed wheel surrounded by one or two pairs of driving magnets.

Muirhead's Motor.—A novel design used by the Eastern Telegraph Co. and made by Messrs. Muirhead and Co. is illustrated in Fig. 57. The stators are cruciform in shape and are bolted to the casing. The rotor is provided with internal teeth and embraces the stator. It is bolted to an aluminium spider AS which is, in turn, bolted to the shaft. FW is the usual mercury flywheel. This construction reduces the overall diameter considerably, as compared with other types.

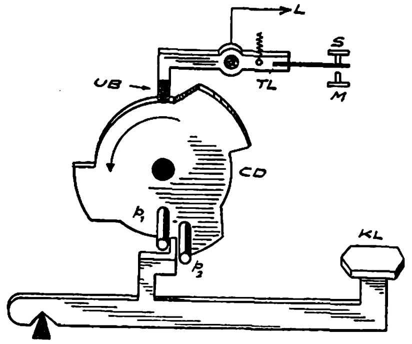

FIG. 59.—Elementary keyboard transmitter.

Distributor Construction.

The influence of American designers on distributor construction has been considerable. In place of the single-face distributor more or less general in Europe, they employ separate distributors for receiving, transmitting, correction and the other purposes that a distributor serves (stepping tape transmitters, synchronizing printer units, etc.)

Western Union Distributor.—Fig. 58 represents a distributor as used on the Emden–New York high-speed cable. Three distributor faces DF_1, DF_2, DF_3 are mounted on a common base. The three sets of brush arms CBA are driven from a main shaft and each can be separately and independently orientated by the hand-wheels PAH by means of differential gears DG. The shaft is driven by a phonic-wheel motor PWM having a mercury flywheel FW. In addition, a d.c. motor DCM is geared to the shaft and the phonic-wheel motor is impulsed and the speed of the d.c. motor controlled by a common fork, as shown in the lower diagram. The combined drive is thus powerful and yet has time-keeping-properties by reason of the tuning-fork control of the two motors.

All connections are cabled to a terminal block on the front of the cast-iron base, and, in use, this is protected by a dust-cover (not shown).

Distributors are driven at from 3 to 6 revolutions per second and phonic-wheel motors have from 6 to 9 teeth. Fork speeds vary therefore from 18 to 60 complete vibrations per second.

Section (2). TRANSMITTERS OR COMPOSING MACHINES.

General Considerations.—There are two general types of transmitter:—

(1) The keyboard controlled transmitter; and
(2) Transmitters of the Jacquard mechanism type, in which the control is effected by a paper fillet or tape.

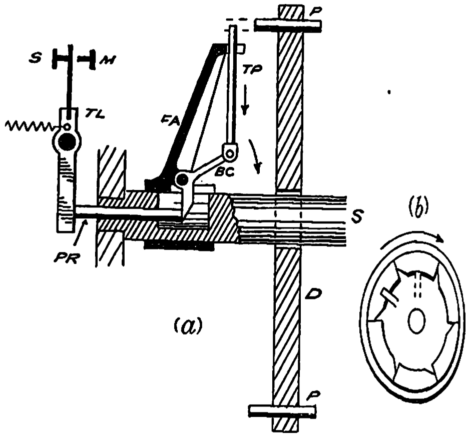

FIG. 60.—Siemens's keyboard transmitter.

Type (1) is not readily adaptable to the transmission of unequal-letter alphabets such as the Morse Code, as it takes its simplest form when the transmitting cycle time is invariable. The second type is equally efficient, regardless of the nature of the code employed. This is due to the fact that the tape forms a storage reservoir which removes the restriction as to the time of the transmitting cycle. Type (1) can be made to approach the universal character of type (2) by adopting metal storage means such as a group of pins in a cylinder or disc, but it then becomes very costly, especially if an unequal-letter code is employed.

The second type of transmitter can be operated either

(i) Continuously, at high speed, where it handles the output from a number of manually-operated keyboard perforators; or
(ii) Intermittently, letter by letter, when controlled by an equal-letter code.

When intermittently operated, the feed wheel is stepped forward by a ratchet-and-pawl mechanism operated by an electromagnet impulsed by contacts on a distributor.

Under these conditions it transmits the output of one keyboard perforator only. It may also be intermittently operated by a shaft released to make one revolution or some even part of a revolution. The shaft is then intermittently clutched to a continuously rotating power shaft and is either coupled to it by a mechanical operation when a key lever is actuated, or it can be controlled from distributor contacts operating a clutch magnet.

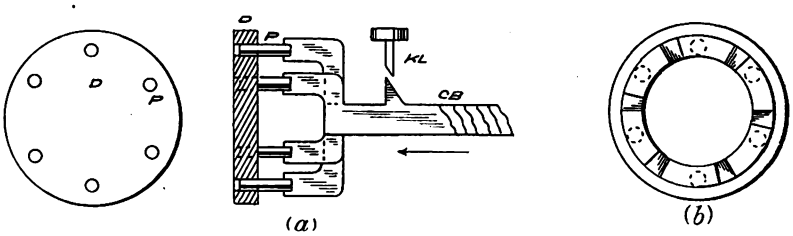

FIG. 61.—Alternative forms of differential cam devices.

Elementary Keyboard Transmitter.—Fig. 59 represents an elementary form of keyboard transmitter in which there are a number of code discs CD corresponding to an equal number of key levers KL. The code discs are friction-tight on a continuously driven shaft, but are restrained from rotation by a lug on each key lever against which rests a pin " p," fixed to the code disc CD. If a key lever is depressed, its restraining lug is moved out of the path of pin " p_1," and the disc is entrained by the rotating shaft through the friction coupling and makes one revolution. If the key lever is kept in the operated position indefinitely, the code disc does not make more than one revolution due to the provision of a second stop pin " p_2" which is caught by the lug on the key lever when the latter is in the operated position. Under these conditions the code disc is not quite in its normal position, but when the key is released the stop lug rises, freeing pin " p_2," but finally stopping the disc by coming into the path of " p_1." As the selected code disc rotates, the projections and depressions oscillate a bar UB which rests on the depressed surface of all the code discs, and this movement controls a single transmitting lever TL to send out marking and spacing currents over the line. The code disc is a copy of the current pattern corresponding to the letter signal transmitted.

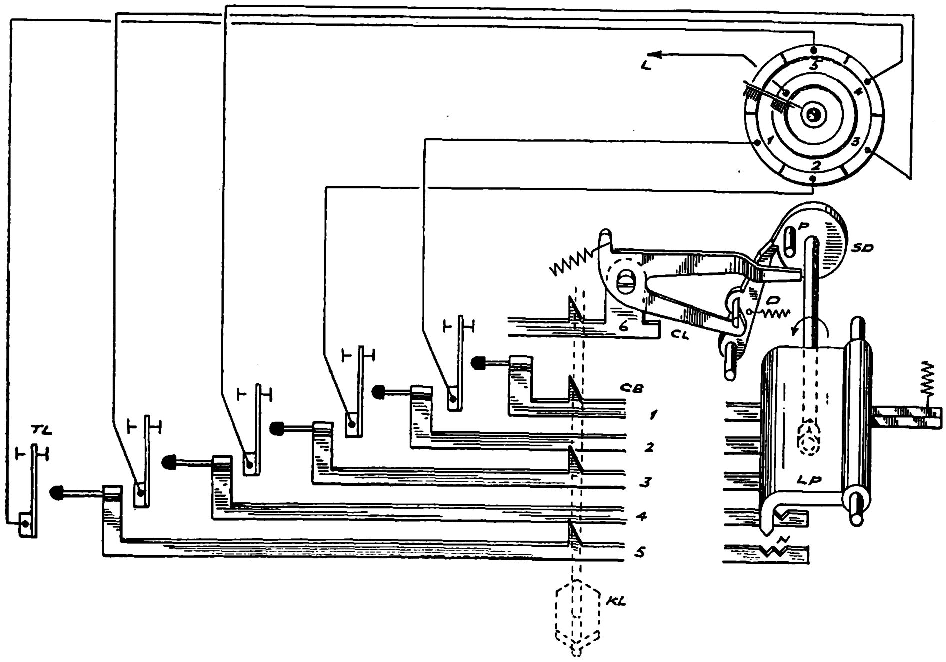

FIG. 62.—Elements of keyboard transmitter.

This type of keyboard transmitter involves:—

Individual code discs for each letter.
An invariable time for the transmission cycle.

It is therefore only applicable to an equal-letter code and, except for the cost of the individual discs, would serve quite well as a means of operating any of the modern start-stop machine telegraph systems.

Siemens's Transmitter.—The individual cams could be replaced by a single cam if it were possible to rearrange the projections and depressions on the edge of the cam by a selective process effected on the operation of any key lever. This was accomplished over 75 years ago by Werner Siemens. Fig. 60(*a*) illustrates Siemens's keyboard transmitter in which the variable cam surfaces are formed by pins P arranged circularly in a disc D, S is a rotating shaft on which is mounted a fixed arm FA which rotates with it. Fixed to FA is a bell-crank BC, to the upper arm of which is pivoted a transmitting pin TP. The lower arm of the bell-crank rests against a presser rod PR which, in turn, rests against the lower end of a single transmitting lever TL. As the pins P are pushed out from their normal position they encounter the pin TP which is momentarily forced below them. As this depression takes place, BC is rocked clockwise and pushes the presser rod PR to the left. PR, acting on the lower end of lever TL, reverses the position of this, and marking current is sent to line.

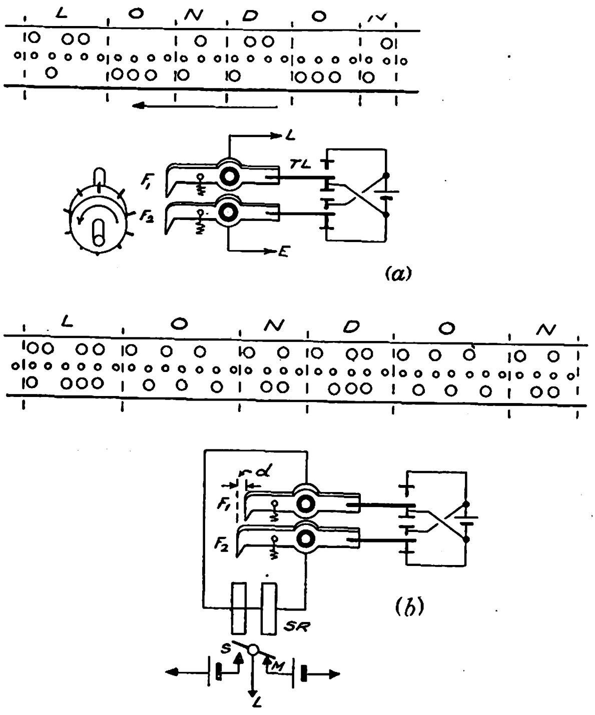

Fig. 63.—Elementary forms of tape-controlled transmitters.

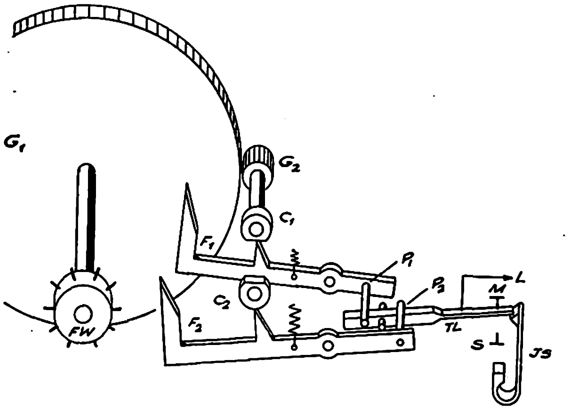

Fig. 64.—Diagrammatic form of Wheatstone transmitter.

In place of the pins, segments capable of displacement out of the plane of the paper may be used, as shown in Fig. 60(*b*). The variable setting of the pins may be accomplished by the usual combination bars set by any one of a number of key levers in accordance with the current permutations representing the letter signal corresponding to the key lever operated [Fig. 61(*a*)]. Fig. 61(*b*) shows the pins replaced by segments. Both arrangements, if the transmitting arrangements of Fig. 60(*a*) are applied to them, correspond to a single code disc to which a differential cam effect can be imparted by the setting action of any one of a number of key levers.

The discs with their pins or segments may revolve and the transmitter lever mechanism be stationary. If, however, the capacity of the disc is only one letter signal, the disc must be stationary during the setting process and clutched to a rotating shaft for one revolution only.

All-electric Keyboard Transmitter.—An all-electric type of keyboard transmitter is illustrated in Fig. 62. The single transmitter lever is here replaced by a distributor with rotating brush-arm. The brush arm is mounted on a shaft which also carries a stop disc SD and a cam which normally keeps a lock plate LP free of the combination bars 1 to 5. Each key lever operates the bars CB variably in accordance with the letter signal to be transmitted. The left-hand end of each bar carries an insulated rod adapted, when a bar is moved to the left, to reverse the position of the 5 transmitter levers singly or in combination. A sixth bar CL is operated by any one of the operated key levers KL and removes the detent D from the single tooth of the stop disc SD. The brush arm, the stop disc and the lock plate cam now start revolving. The lock plate drops and its front edge enters one of two notches N in the combination bars, thus locking them in their operated and non-operated positions so that premature release, by the operator, of the key lever which has been depressed cannot mutilate the signal. Indirectly it locks the keyboard, as the depression of a second key while the first is down is without effect. As the rotation of the shaft, yieldingly driven by a motor—not shown—proceeds,

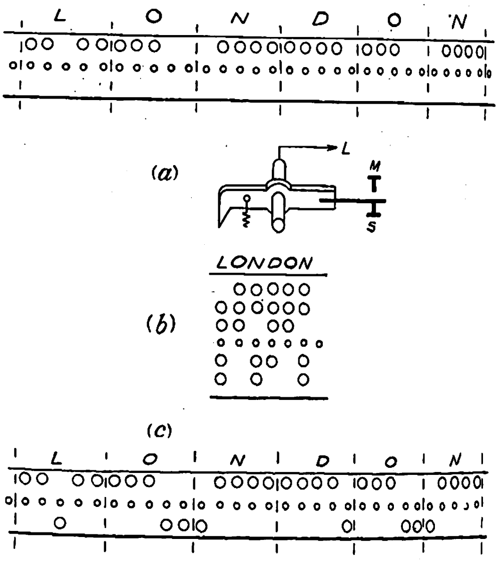

Fig. 65.—Various forms of 5-unit transmitting tape.

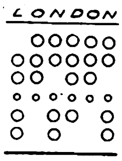
the letter signal pulses are swept out to line by the distributor as the brushes make contact successively with the segments to which the transmitter levers are connected. At an early stage of the revolution, a pin P on stop disc SD comes in contact with the upper arm of the bell-crank attached to the sixth bar CL. As P moves downwards it depresses the bell-crank until its lower arm is clear of the pin on the detent D. The latter, thus freed, is drawn to the right under the action of a spiral spring and is ready to arrest the stop disc and brush arm when the single tooth comes round at the end of the revolution. Thus the key lever may be kept down indefinitely, but the letter signal will only be transmitted once. At the end of the revolution, the lock plate is lifted by its cam and the keyboard is unlocked, thus becoming free for the setting up of another letter.



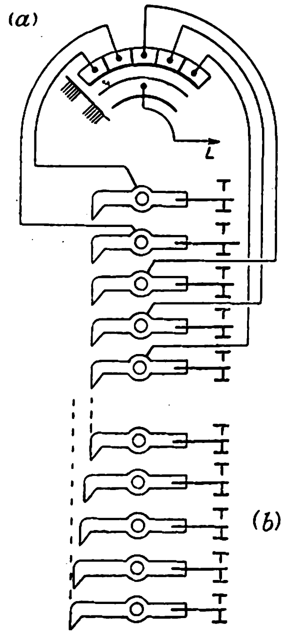


FIG 66.—Alternative forms of 5-unit transmitter.

This elementary form of keyboard transmitter illustrates very well the conditions which have to be met in start-stop machine telegraphy. These are:—

Only one letter signal must be sent out when a key lever is actuated.

The keyboard must be immediately locked when a key is operated so that:—

(a) Premature release of the key does not mutilate the signal, and

(b) The improper depression of another key, while transmission is proceeding, is without effect.

Tape-controlled Transmitter.—The second type of transmitter, controlled by a perforated paper tape, takes a variety of forms depending upon the code of signals to be transmitted. Fig. 63 represents in elementary forms the cable Morse Code transmitter and that for land-line Morse Code or Wheatstone Code. Each transmitter is provided with a pin or sprocket wheel which is rotated through gearing by a suitable motor and engages the centre line of small feed-holes formed in the tapes by the perforating mechanism. Each transmitter is provided with two feelers F_1 and F_2, insulated from one another and from a common pivot, and so placed with respect to the paper tape that their noses are pressed downwards on this, which is supported on a platform (not shown). The cable code is such that signal perforations occur both above and below the centre line of feed holes with portions of imperforate tape representing spaces between the letters. It will be noted that on any vertical line across the tape only one hole can occur, but that it may be either above or below the line of feed holes. The feelers explore across the tape and along any one of the imaginary vertical lines, and since there are two possibilities the exploring action of the two feelers must be simultaneous. If either feeler encounters a perforation it is forced into it and, oscillating on its pivot, reverses the position of its transmitting lever TL.

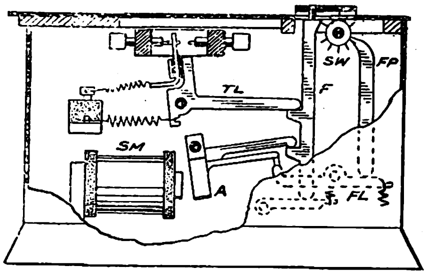

FIG. 67.—Step-by-step 5-unit transmitter.

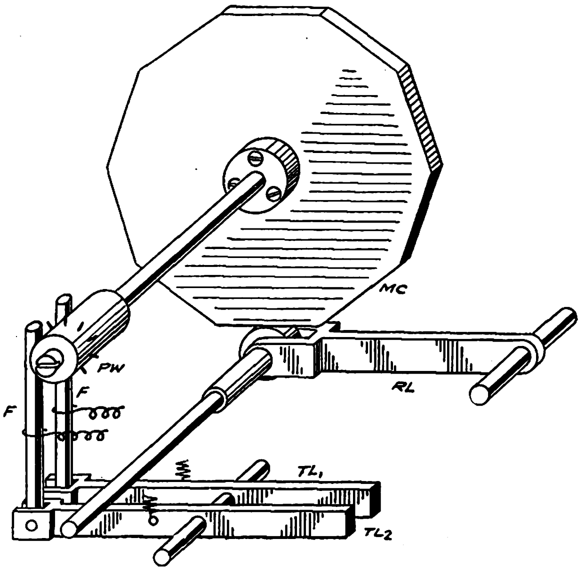

FIG. 68.

In the case of the land-line morse, two holes do occur in the same vertical line on the tape [Fig. 63 (*b*)]. The simultaneous operation of the two feelers would then be ineffective, as both transmitter levers would be connected to one pole of the battery, while the other would be insulated. The feelers in this case have their noses displaced by a distance *d* equal to half the pitch of the feed holes in the tape. As the tape moves from right to left, feeler F_1 enters the first hole in the top row and half a centre hole-space later is rejected, while F_2 enters a hole in the lower row if one exists. Such a case as this occurs on the first vertical line of the letter L in the word "London." A positive marking signal is first sent out, followed by a negative spacing signal, these two pulses constituting a morse dot (double-current operation). The next signal is a dash, which consists of an upper hole opposite to which is an unperforated portion of tape succeeded by an upper unperforated portion opposite which is a hole in the lower portion. The effect on the feelers is as follows:—F_1 falls into the top hole and reverses the position of the tongue of the sending relay SR so that this sends positive (marking) current to line and initiates the dash signal. SR, being a polarized relay, remains in this position, and as the tape advances F_1 is rejected and held against its lower spacing contact. SR is not interfered with.

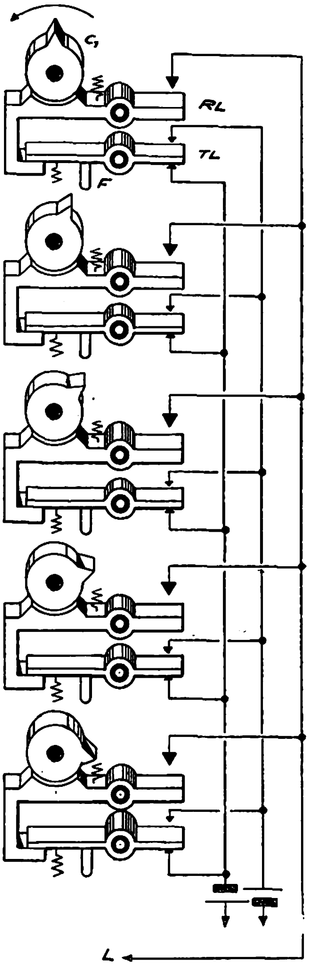

FIG. 69.—Baudot's 5-unit transmitter.

As the tape advances further, feeler F_2 encounters the lower hole, reverses its position and sends a current through the sending relay in a direction to move the tongue to the spacing contact S. This elementary transmitter only initiates the beginning and end of a signal, dot or dash, the sending relay ensuring that these are of full length by its property of remaining on whichever contact it is placed until receiving a pulse to reverse this.

Wheatstone Transmitter.—The well-known Wheatstone transmitter does not require a sending relay as its two peckers control the movement of a transmitting lever which is mechanically held on the contact on which it, at any moment, rests.

Fig. 64 gives the principles of the transmitter in diagrammatic form. A weight or other form of motor drives a gear wheel G_1, which is rigid on a shaft provided with a pin feed wheel FW. A second shaft geared to the first carries two cams C_1 and C_2 which alternately depress and release two feelers F_1 and F_2 pivoted to the framework of the transmitter. Cam surfaces on the feelers are kept up against cams C_1 and C_2 by spiral springs. At the right-hand ends of F_1 and F_2, pins P_1 and P_2 act alternately on a pivoted transmitting lever TL. The latter is held on either contact, M or S, by a jockey spring JS. The operation of the transmitter will be obvious from the preceding matter. The gear ratio is such that one signal cycle takes place while FW moves through the angle between two feed pins.

Five-unit Code Transmitters.—Perforated tape for the 5-unit code takes three forms. Fig. 65(*a*) shows one such in which the letter signals are parallel to the line of feed holes. A single-lever transmitter is successively actuated as the tape is drawn past the pointed end of the feeler. Fig. 65(*b*) shows a tape in which the letter signals are at right angles to the feed holes or across the tape. This effects economy in tape but requires a different type of transmitter. Fig. 65(*c*) shows a form of 5-unit tape in which marking and spacing holes are on opposite sides of and parallel to the line of feed holes. This tape is of the same form as a cable code tape and the transmitter shown in Fig. 63(*a*) can be used with it.

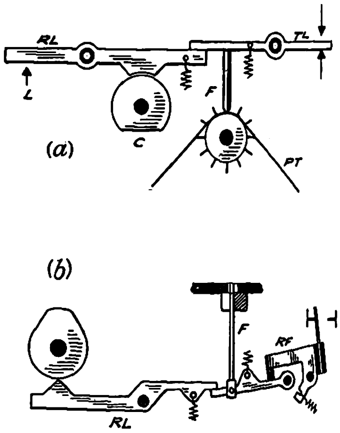

FIG. 70.—Kleinschmidt's 5-unit transmitter.

The transmission of cross-perforated tape is effected in two ways. The tape may be fed forward letter by letter, feeding taking place after the letter has been transmitted. Five transmitter levers are used in this case, each being connected to a sending segment on a distributor (Fig. 66*a*). The second method is to feed the tape continuously forward by a pin feed wheel suitably geared to the distributor brush-arm shaft. The feelers must then operate in succession and are therefore varied in length [Fig. 66(*b*)] to secure this.

A well-known type of step-by-step transmitter is shown in Fig. 67. Five feelers F, side by side, control five transmitting levers TL. SM is the stepping magnet which, when energized, withdraws all the feelers from the tape and acts on a feed lever FL to raise the feed pawl FP which moves the star wheel SW through an angle so that the latter draws the tape on one feed hole in extent.

In a cable code transmitter it is now general practice to use a phonic-wheel motor controlled by a tuning fork in order to obtain that constancy of speed which is so necessary for cable working. By using a multiple-faced cam for controlling the feelers, the motor may be applied directly to the transmitter without the use of gearing. Fig. 68 shows the arrangement, which is due to Messrs. Muirhead and Co.

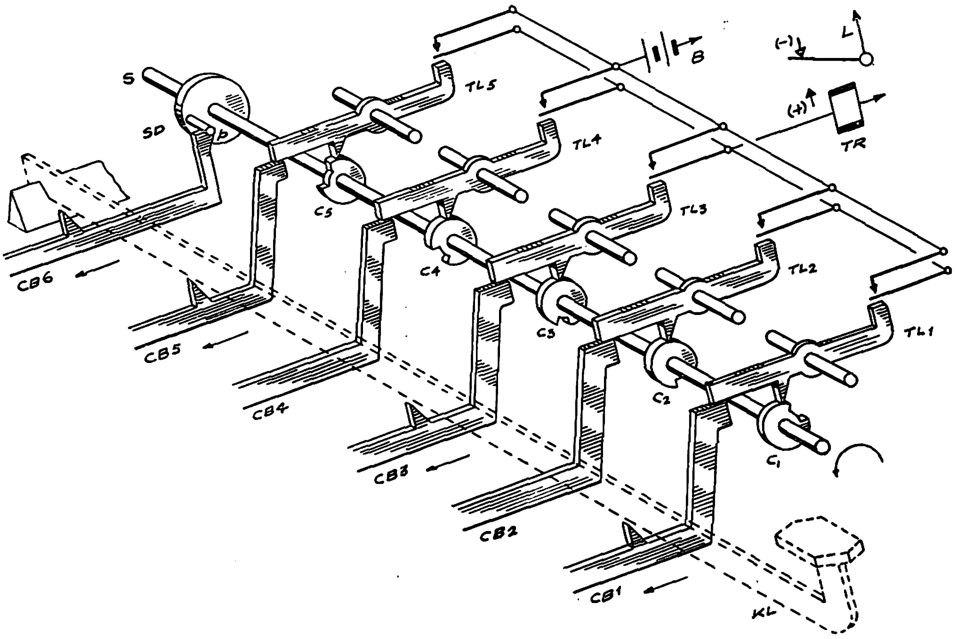

FIG. 71.—Principle of Morkrum's 5-unit keyboard transmitter.

In all the types of tape-controlled transmitter so far examined, the following charactersitics will be noticed:—

Wherever a cross-perforated tape, of the type where more than one perforation occurs on the same vertical line, is used, the transmitter feelers must act in succession.

Where more than one feeler is used, they may have individual transmitter levers or may act separately on a single transmitter lever.

The perforated and unperforated portions of the controlling tape constitute the equivalent of the cams of Fig. 59 and, in the case of equal-letter codes, may be considered as a single cam with its cam faces variably adjusted.

Baudot's Transmitter.—In 1880 Baudot designed a transmitter for cross-perforated tape in which 5 feelers (Fig. 69) attached to individual transmitter levers TL are released in succession by means of a series of release levers RL, and allowed to explore the series of perforated and unperforated portions of tape lying immediately beneath them. Levers RL are depressed successively by a series of cams C_1 to C_5 and connect the line to the transmitting levers in turn. The currents sent out to line will depend upon the letter signal punched in the tape and presented to the feelers. The release levers not only allow the entrance of the feeler into a perforation and reject it subsequently, but as they also connect the line to the feelers one after the other they replace the usual distributor and the mechanism may be termed a "transmitter-distributor," although Baudot described it as a "mechanical distributor."

If we rearrange Baudot's transmitter somewhat as in Fig. 70(*a*), it is still identical with Fig. 69, in principle, the tape feed wheel and perforated tape PT now being shown.

Fig. 70(*b*) represents a well-known type of 5-unit transmitter in which the only variation from Fig. 69(*a*) is that the feelers are connected to pivoted levers, and oscillate a rocking frame RF on which is mounted a single transmitting lever moving between spacing and marking contacts.

This transmitter of Baudot shows that the first principle relating to tape transmitters is perfectly general and not restricted to any particular number of cross-perforated holes. Also, it will be seen that in such transmitters where the feelers are operated in succession through one signal cycle the tape produces an interference effect—where unperforated portions occur—and constitutes a series of variable cams. Thus if each letter signal during one revolution of a battery of cams is caused to operate a number of transmitting levers or not, according to whether the motion of these is interfered with, the modern keyboard transmitter is arrived at.

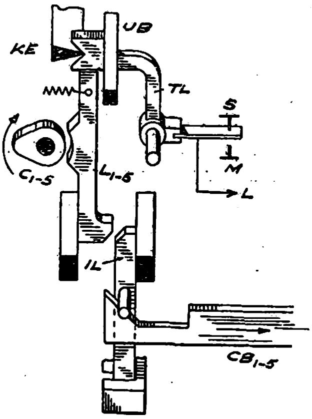

FIG. 72.—Potts's 5-unit keyboard transmitter.

Morkrum's Transmitter.—An example due to Morkrum is illustrated by Fig. 71. S is a shaft yieldingly driven and arranged to be stopped and started by means of a combination bar CB_6 set by a plurality of key levers of which KL is one. Five two-armed transmitting levers TL_1 to TL_5 are adapted to close the circuit of a battery B by which a transmitting relay TR sends positive marking or negative spacing currents over a line L. If the whole of the combination bars are shifted to the left in the direction of the arrows, they will have no interfering action on the transmitter levers and the latter will successively fall into the depressions on cams C_1 to C_5, thus causing 5 positive pulses to be sent out to line. If a combination bar is not withdrawn it will interfere with its own transmitter lever and this cannot fall into the depression of the corresponding cam. Thus, a battery pulse from B will be suppressed and transmitting

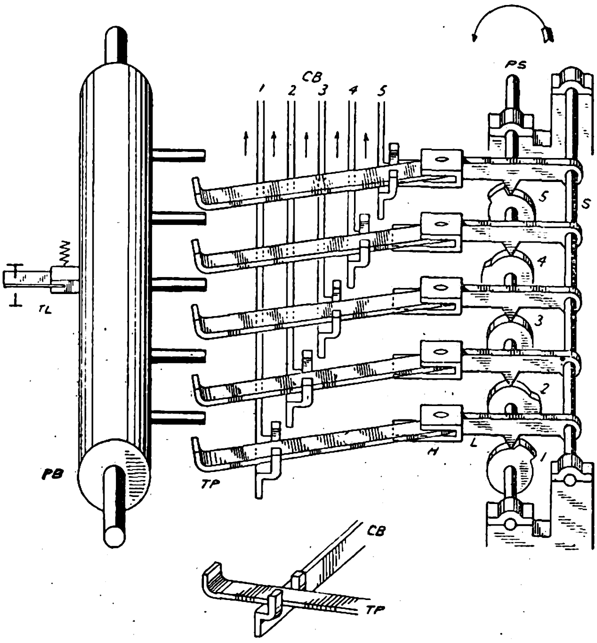

FIG. 73.—Cardwell's 5-unit keyboard transmitter.

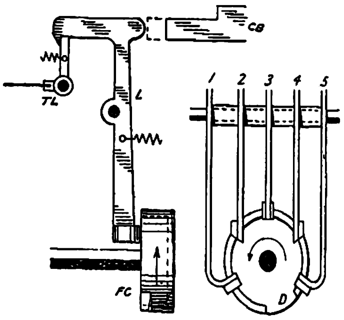

FIG. 75.—Siemens and Halske's 5-unit keyboard transmitter.

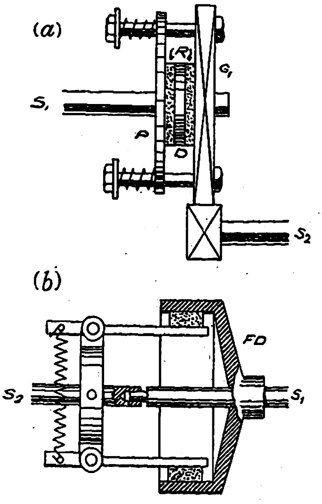

FIG. 76.—Alternative forms of friction clutch.

relay TR will release sending a negative or spacing current to line. This transmitter is in principle identical with that of Baudot, the cam surfaces, when not selected, acting as unperforated portions of the controlling tape used by him.

Potts's Transmitter.—A single transmitting contact lever may be used, as shown in the construction of Fig. 72 due to Potts. Here, 5 levers pivoted at their upper ends on a knife edge KE are successively operated by a series of 5 cams, and act upon a single transmitting lever by means of a universal bar UB. Normally, the lower ends of the vertical pivoted levers are free and when the cams come into contact the lower ends of the levers are pushed to the right, KE acting as a fulcrum.

The combination bars CB_1 to CB_5, when displaced, raise intermediate pieces IL which cause the levers L_1 to L_5 to fulcrum on these, so that when a cam is now active the upper ends of the levers are moved to the right and, acting on UB, reverse the position of TL to send a marking current. These selections are variable in accordance with the letter represented by the key lever operated.

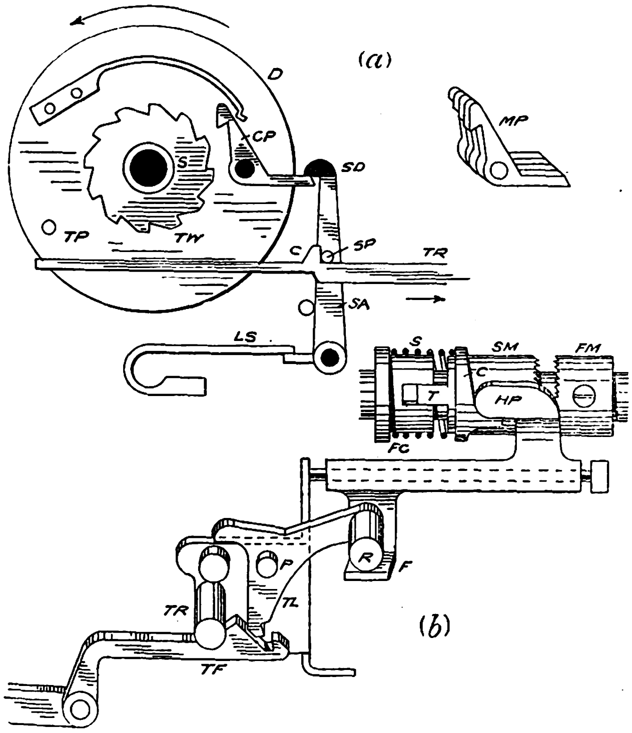

FIG. 77.—Alternative forms of single-revolution clutch mechanisms.

Cardwell's Transmitter.—Cardwell's single-contact keyboard transmitter is illustrated by Fig. 73. The transmitting lever TL is controlled by a pin barrel PB which is rocked at appropriate instants by a series of cam-controlled levers L having hinges H to which are attached a series of plates TP which can be selectively brought under the pins on the barrel by means of the combination bars CB. As the corresponding lever L is raised by its cam, the hinged plate TP, if under one of the pins in the barrel PB, rocks the latter and reverses the lever TL.

Kleinschmidt's single-contact transmitter (Fig. 74) consists of a barrel B capable of rotation and also endwise motion. It is provided with 5 cams arranged spirally and these engage other cams at the ends of selected combination bars which shift the barrel endwise, reversing the position of the transmitting lever TL.

Siemens and Halske's transmitter is shown in Fig. 75. In this apparatus, 5 levers L act on a common transmitting lever TL and are freed in succession by a cam FC having a single depression D. Combination bars CB interfere with the movement of levers L, if they are in the selected position.

Single-revolution Clutches.—The transmission, letter-by-letter, of equal-letter codes from a keyboard transmitter necessitates means by which the cam shaft makes one revolution per letter. It is not practicable to start and stop a motor revolution by revolution, and consequently means have to be provided by which the cam shaft is coupled to the power shaft for a single revolution. Clutches for this purpose may be broadly divided into two classes:—

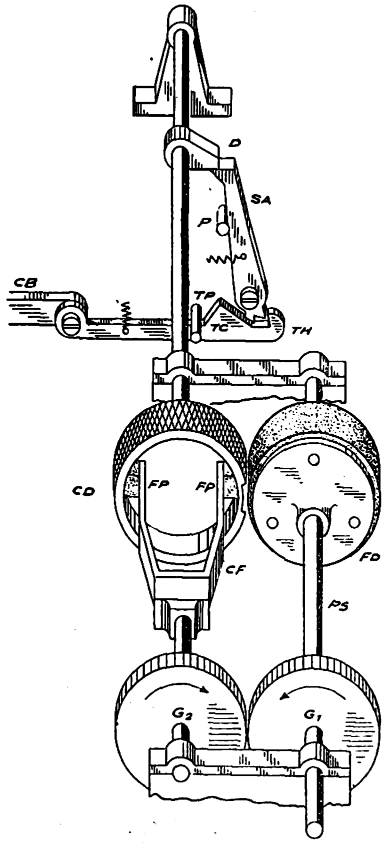

FIG. 78.—Single-revolution 2-stage friction clutch.

> Friction clutches in which the cam shaft is positively stopped against the couple exerted by the clutch, and
>
> Positive clutches in which the shafts are mechanically connected and forcibly uncoupled when the single revolution is completed.

The coupling action must be effected when a key lever is operated, and must be independent of the duration of key-lever operation. Two types of friction clutch are shown in Fig. 76. Their operation is obvious. Two examples of the positive type of clutch are shown in Fig. 77. In Fig. 77(*a*) the power shaft is in the form of a sleeve S and carries a toothed wheel TW. S and, with it, TW, are continuously rotated. The cam shaft is surrounded by the sleeve S and carries a disc D on which is mounted a spring-pressed coupling pawl CP. CP is normally clear of TW, being held so by a stop detent SD. When a key lever is operated it pulls a trip rod TR to the right. TR is provided with a cam C which acts on a pin SP and withdraws the detent SD from the tail of the coupling pawl SP. CP, under the control of the curved spring, forcibly enters the teeth of wheel TW, coupling sleeve and cam shaft together. The tripping mechanism is now reset independently of the operation of the key lever in the following manner. A pin TP on disc D engages the free end of the trip rod TR and frees it from SP so that the detent SD immediately flies back to the stop position in readiness to act on the tail of CP and uncouple the sleeve and cam shaft when the revolution is completed. The momentum of the moving parts assists the uncoupling operation. When the key lever is finally released TR returns under the action of a spring to the normal position shown. To ensure prompt coupling action a multiple pawl is sometimes provided, as shown in the inset, and a number of similar wheels equal to the number of pawls, but with their teeth staggered, are employed.

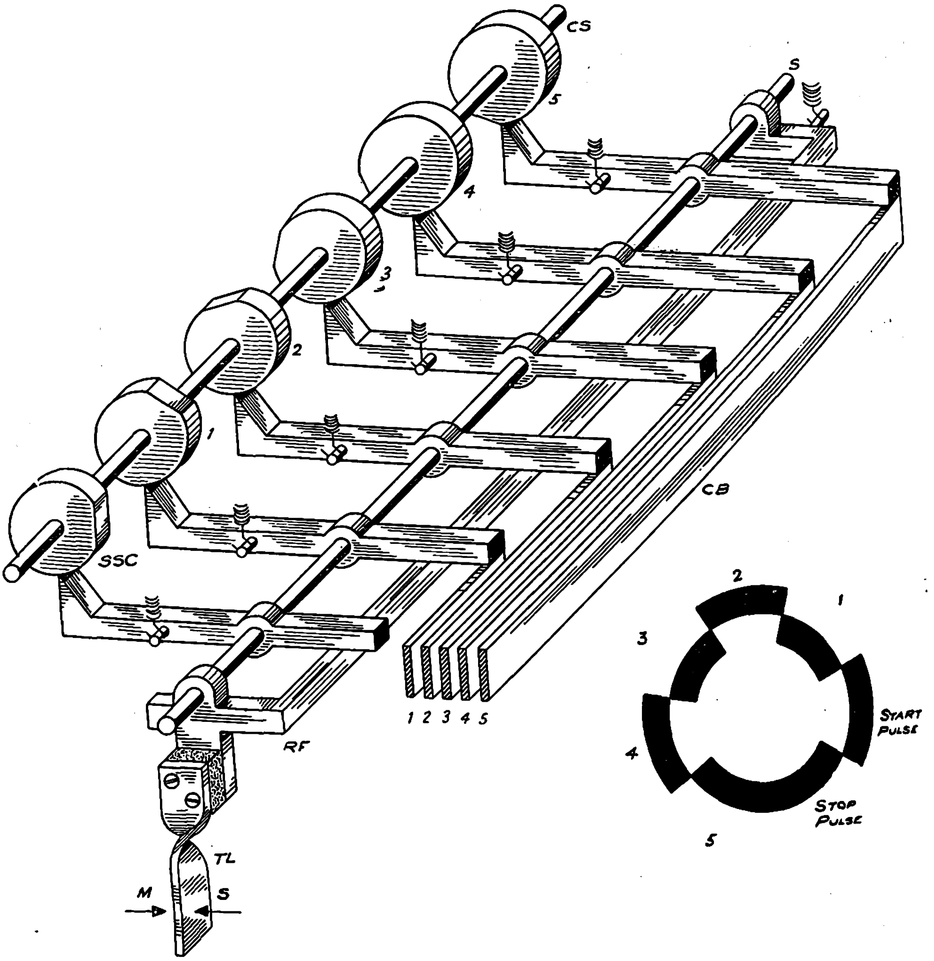

FIG. 79.—Creed's 5-unit keyboard transmitter.

Fig. 77(*b*) shows a keyboard-controlled clutch mechanism, in which the clutch is formed by two circular toothed members, one, FM, fixed to the revolving shaft and the other consisting of a spring-controlled sliding sleeve SM. The latter is coupled by means of tongue T to a fixed collar fastened to the cam shaft. Release is effected by a holding pawl HP which is released and reset by the trip mechanism shown and which acts on a cam C to uncouple SM at the end of the revolution.

Friction clutches have the disadvantage that they cannot deal with a heavy load. If they are arranged to do this, then the force required to stop them is considerable and the wear on the friction coupling is excessive. If they are to start up the secondary shaft promptly when release is effected, they must exert considerable torque and the release then becomes difficult, while the stoppage occasions violent shocks.

A friction clutch which meets the conflicting requirements very ingeniously is shown in Fig. 78. The power shaft is geared by wheels G_1, G_2 to the clutch fork CF the extremities of which carry friction pads FP engaging with the internal walls of a coupling drum CD. CD is mounted on the secondary shaft which is restrained from movement by detent D. Release is effected by the usual tripping arrangement, as shown, and CD commences to revolve. Directly it has moved through a small angle the knurled outer walls of the coupling drum engage an auxiliary friction disc FD on the power shaft and additional power is supplied to drive the secondary shaft. Towards the end of the revolution, the slot in the outer wall of CD comes opposite to FD so that the latter is no longer in contact, and the secondary shaft can be stopped with comparatively little effort. The clutch is thus made sensitive with respect to the start or stop conditions and yet is able to transmit adequate power to the secondary shaft.

Modern Start-Stop Transmitter.—The leading features of the modern start-stop transmitter are set out in Fig. 79. The transmitter sends out a start pulse, the 5-letter signal pulses and a stop pulse. Six cams are provided, mounted on a shaft CS, and they engage the noses of 6 horizontal spring-controlled levers mounted on a shaft S. Suspended on the same shaft is a rocking frame RF carrying a single transmitting lever TL.

If the horizontal levers are unrestrained they will oscillate counter-clockwise in succession and operate the rock frame so that it reverses TL. They are, however, variably interfered with by the combination bars CB in the usual way. This construction is due to Creed.

If the transmitter had been tape-controlled the cams would have been replaced by a paper tape and the horizontal levers provided with feelers or peckers.

Classification of Tape-controlled Transmitters.—Most transmitters of the tape-controlled type are operated indirectly, the tape being the controlling means by which the transmitter lever is power-driven from one position to the other.

Fig. 80(*a*) represents the well-known Wheatstone transmitter in which a rocking beam alternately presents a pair of peckers to the perforated tape. The transmitting lever is shifted by means of the energy stored in the springs controlling the bell-cranks, and this energy is obtained from the transmitter motor. Fig. 80(*b*) represents the Willmot transmitter for cable code. There are two bell-cranks and two levers TL but only one of each is visible, as one set is behind the other. Fig. 80(*c*) shows Stonell's cable code transmitter and Figs. 80(*d*) and (*e*) are arrangements due to Muirhead. Fig. 80(*f*) shows an arrangement of reciprocating means due to John Gell which consists of a pin disc in place of the reciprocating beam. It reduces the necessity for gearing. A considerable simplification in transmitter mechanism is secured by adopting reciprocating cams of the type shown in Fig. 80(*g*). They would be mounted on the shaft carrying the small eccentric E shown in Fig. 80(*a*).

Fig. 81(*a*) shows a cable code transmitter employing two sending relays SR_1 and SR_2. These are provided with operating and reset windings OW and RSW. In transmitters of the cable code type it is only possible to get 50 per cent marking for a complete signal element. By adopting the arrangement shown, the percentage of marking can be varied between 50 and 100 per cent. RD is a revolving disc on the transmitter shaft having two groups of segments. Once the sending relays are set they would remain so indefinitely if they were not reset, and the reset condition is controlled by RD. The reset circuit is formed via brush B, segment " b," a second segment " b " and brush A to negative. By moving brush A, carried on arm PA, backwards or forwards, the amount of coincidence of A and B can be varied and thus the time at which the relays are reset and the cable put to earth. A scale " s " enables the degree of marking and earthing to be known for any position of PA.

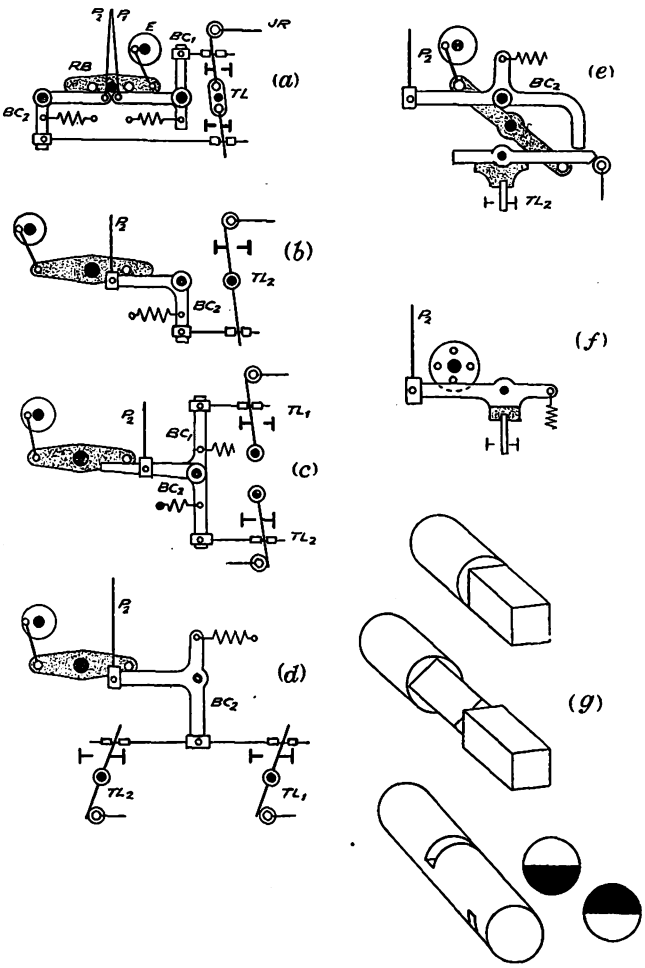

FIG. 80.—Various forms of Wheatstone-type tape transmitter.

In Fig. 81(*b*) the same effect is obtained mechanically by a cam C_2 which can be orientated with respect to cam C_1. Fig. 81(*c*) shows an arrangement by which a curbing battery is employed so that a current in the opposite direction is sent towards the end of a signal element. The proportion signal curb is varied by means of an adjustable cam arrangement shown in Fig. 81(*d*).

Transmitter levers are subject to bounce and also have a definite transit time. These have a distorting effect on the outgoing signals and a disturbing effect on the duplex balance. It is a well-established fact that

FIG. 81.—Curbing arrangements for cable-code transmitters.

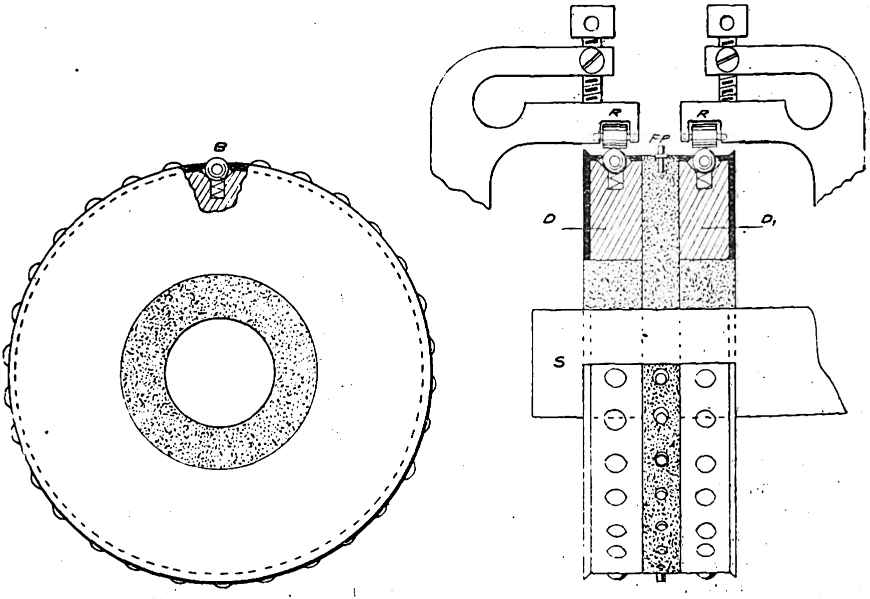

FIG. 82.—Riddle's high-speed cable-code tape transmitter.

the most perfect signals are obtained from a distributor. The reason for this is, of course, that the transmitter levers are already set and quiescent before transmission and there is no transit time.

It is becoming general practice now on long lines to employ the method of transmission shown in Fig. 81(*e*). The transmitter levers set up the signal elements alternately on two sending relays SR_1 and SR_2 via a distributor, and the signals are sent out one signal element later by a second set of distributor segments. The arrangement is identical with the regenerative repeater and amounts to placing this directly at the transmitter.

The high-speed cables in existence nowadays have been operated with cable Morse Code, while other methods of operation have been under trial. This has necessitated modifications in the design of both transmitters and receivers in order to take full advantage of the signal capacity of the cable (2 000 to 2 500 letters per minute). The ordinary Wheatstone transmitter will not stand up to these speeds when continuously operated, and an interesting departure is the transmitter constructed by the Telegraph Construction and Maintenance Co. and invented by Mr. John Riddle.

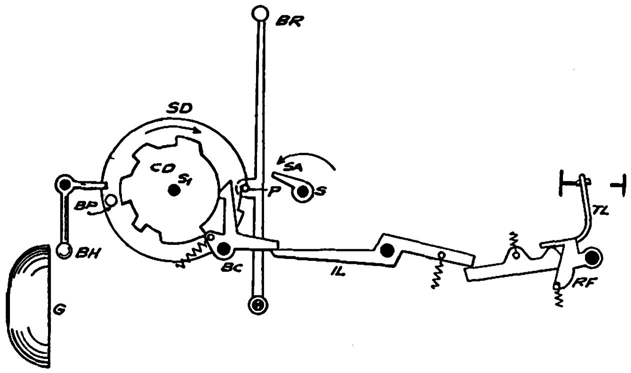

FIG. 83.—Kleinschmidt's bell-ringing arrangement for 5-unit code tape transmitters.

It consists (Fig. 82) of two discs D and D_1 in the periphery of which are a number of holes housing balls B. These balls are each pressed outwards by a spiral spring but are kept in position by two flanged discs, seen in the sectional view. The discs are insulated from the shaft S on which they are mounted and are also insulated from each other by an insulating centre disc in which are screwed the feed pins FP for propelling the tape. Opposite to each line of balls are two spring-pressed rollers R which, with the balls and discs, form part of the signalling circuit. The tape passes between the rollers and balls and, where perforations occur, the signal circuit is closed. The ability of this transmitter to operate at high speed is due to the use of a number of transmitting mechanisms (the spring-pressed balls) in succession, so that these have after use practically the whole of a revolution in which to reset themselves to normal. On the Bay-Roberts–Fayal cable good signals were obtained with this transmitter at 2 500 letters per minute and for over a 3 weeks' run no trouble arose. The balls help in the propulsion of the paper tape and as a result of this an endless band of slip, 8 ft. long, was run for 8 hours at 2 000 letters per minute without any sign of wear. This would be an impossibility with the ordinary type of transmitter, and speaks well for the operating qualities of the Riddle transmitter. The apparatus is also provided with means for varying the periods of marking and earthing, and, in addition, provides for periodic synchronizing signals when there is no tape in the transmitter, a condition necessary where regenerative repeaters are employed.

Bell Signalling on Start-Stop Transmitters.—Five-unit code tape transmitters controlling start-stop receivers and of the type which run continuously, sending out start and stop signals with the letter signal pulses, are arranged to be stopped between the transmission of adjacent letters for the purpose of sending bell-code signals for service purposes. One method of doing this is the arrangement of Kleinschmidt, shown in Fig. 83. SA is a stop arm mounted on shaft S which carries the transmitter cams, not shown. If bell rod BR is moved to the right a pin P mounted on it encounters SA and stops transmission at the right point between two letter signals. At the same time SD, which is yieldingly driven and is mounted on shaft S_1, is released. S_1 carries a code disc CD which, in one revolution, sends out the figure-shift signal, a secondary signal which rings a single-stroke bell at the distant printer and the letter-shift signal. This will continue as long as BR is held to the right, and the transmitting operator is advised of the number of bell signals sent by a pin BP on SD flicking a hammer BH so that it strikes a gong G once for each revolution. The code disc operates a bell-crank BC which by an intermediate lever IL controls the rocking frame RF carrying the transmitter lever TL. The tape-controlled intermediate levers, not shown, have no effect on TL while SA is held stationary.

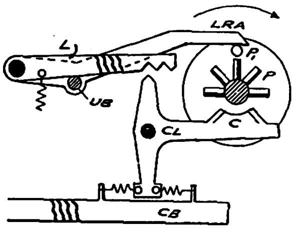

FIG. 84.—Kleinschmidt's mechanical overlap for keyboard transmitters.

Overlap on Keyboards.—Where a transmitter keyboard is free during the transmission of a letter signal, it is desirable to provide means by which a preliminary storage of one letter can be effected. This is to take care of sudden increases in the rate of operation due to a favourable sequence of letters occurring in a message being transmitted. An arrangement due to Kleinschmidt is shown in Fig. 84. Five combination bars CB control a similar number of cam levers CL arranged to impart end-wise motion to a pin-barrel type of single-contact transmitters. When a letter is set up a pin P_1, on a disc revolving with the pin barrel, moves out of the path of a latch release arm LRA which lowers a universal bar UB, allowing the latches L to fall and lock the cam levers either in their operative or non-operative positions. The keyboard is now free for another letter, since, although all the levers CL are locked up, the movements of the bars CB into the new letter signal combination are stored in the small springs coupling the bars CB to the levers CL. As soon as the previous letter has been transmitted, P_1 raises LRA, freeing the latches L, and levers CL can now set themselves in the new combination under the action of the coupling springs.

Condensers as storing means have also been proposed for obtaining overlap on keyboard transmitters.

Receiving Perforator Transmitter.—It is sometimes necessary to retransmit from one channel of a multiplex morse or cable code system to a line which cannot be directly connected to the multiplex system. This can be done by storage relays, but the most efficient means is a receiving perforator which perforates a tape in accordance with the signals received. The Creed receiving perforator is too well known to need description, but in Fig. 85 a simple receiving perforator for cable code invented by Foll is diagrammatically explained. The perforator operations are controlled by the joint action of a centre-zero relay and the local segments of the main distributor. The first part of a signal pulse is utilized to effect the punching process by means of the dot-and-dash punch magnets PM_1 and PM_2, while the second part of the pulse operates the feed magnet FM. FM controls an escapement E and releases a yieldingly-driven shaft carrying the feed wheel. The motor shaft and the perforator shaft are coupled to each other by a permanent magnet on one and a soft-iron fork on the other embracing the magnet, as shown in the inset. This forms an effective and simple method of providing a yielding drive of the character necessary to propel the perforated tape.

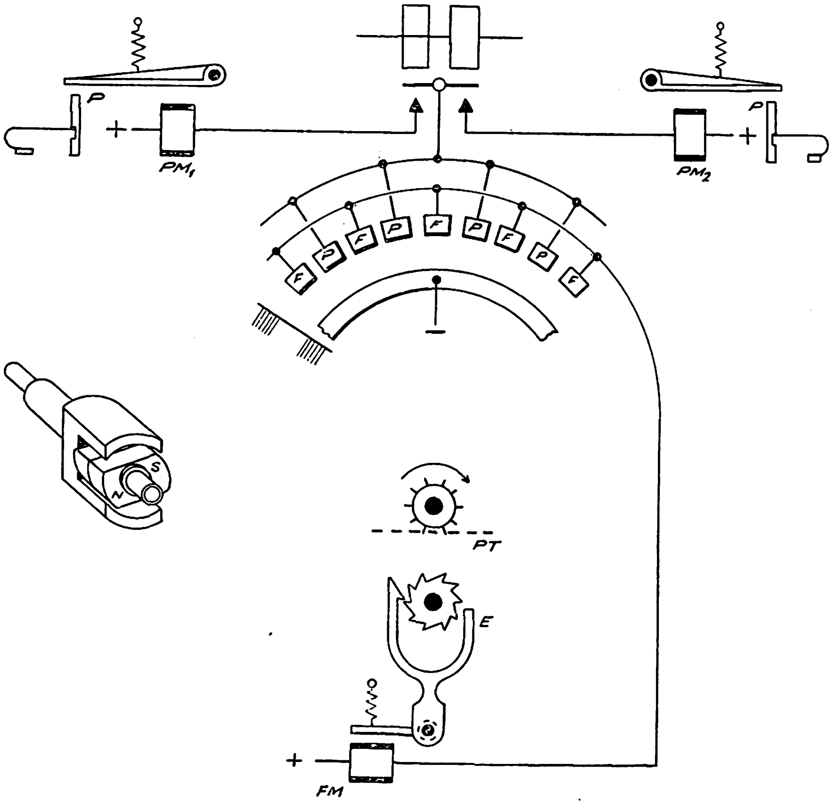

FIG. 85.—Foll's cable-code receiving perforator.

Rational Keyboard Design.—One feature of keyboard design which appears to be thoroughly bad is the small circular key tops taken from typewriter practice. The typewriter keys are small and round in shape and unsuitable for human fingers. The five fingers of the hands are of different lengths and the typewriter keyboard is irrational in this respect and is unsuitable for touch typing operation. The typewriter keys must be operated with sufficient force to operate the entire mechanism—type bar and spacing—and must be hit with a staccato touch and immediately released to clear the way for the next type bar and for carriage and ribbon to move on. There are no such requirements in keyboard transmitters or perforators.

A practised pianist will depress with one hand twice as many keys in a given time as a typist with two hands. He will, for instance, depress 12 keys per second while playing the accompaniment with his left hand. The keys on a pianoforte are long and broad. It is suggested that keyboard transmitter or perforator keys should be large and square and correspond to the length of the fingers, and be so arranged that each finger rests naturally on the key. The proper position for the fingers will thus be found without looking at the keyboard. The keys should be arranged in three rows and on the same vertical line to facilitate selection from row to row, while the pressure and play of the keys should be reduced to a minimum. In this way we shall approach to the sure aim and dexterity of the pianist. If a pianist made as many errors in fingering as does the average typist a public pianoforte recital would be an impossibility.

Evolution of Modern Transmitter.—The modern transmitter has been shown in this section to have been evolved from the single transmitter lever controlled by a plurality of code discs each associated with a character key lever, to a comparatively small number of code discs or cams each representing one signal element of the code. These code discs or cams are operative or not, accordingly to whether their action is interfered with by a second set of cam members furnished either by a number of pins set by code bars controlled by individual key lever bars, or by projections on the code bars themselves, or by a paper tape having perforated and unperforated portions either along or across it. Where a tape transmitter is used the combination of keyboard perforator and transmitter, strictly speaking, constitutes the transmitter proper, the two parts being indirectly associated by the tape and being capable of different and partly independent rates of operation.

The Wheatstone transmitter with its single transmitting lever and the modern 5-unit transmitter are fundamentally identical and only differ in arrangements imposed by the codes employed in the two cases.

Section (3). THE TRANSLATOR OR RECEIVING MECHANISM.

General.—Printer mechanisms have remained essentially the same during the last few years. Combination bars or discs have been employed, set by 5 electromagnets from the usual multiplex type of distributor.

There are two general types—one in which the selection from among 5 combination bars is used to choose a type bar which is forcibly driven against the paper platen by a cam-driven actuator clutched to a power shaft at the right moment. The Murray and Morkrum machines are examples of this class. Combination discs may be employed to set up a differential stop device which stops a rotating type-wheel with the desired letter at the printing point. The Creed printer furnishes an instance of this type. In America the type-bar machine is now modified to print on a tape instead of a page, experience having shown that the maintenance costs of page printers are very heavy.

Single Selecting Magnet.—The really fundamental change in practice is the revival of a 50-year-old idea, viz. the use of a single magnet and a battery of cams acting in succession on a series of selector bars or discs according as the magnet is in the operated or unoperated condition during a signal element.

Baudot's Methods.—In 1878 Baudot invented and constructed the single-magnet translator diagrammatically indicated in Fig. 86.

A tee lever TL pivoted at "x" has pivoted to its right-hand end a forked rod FR. There are 5 such rods and levers. By means of a cam C_1 the tee lever is forced downwards by the raised surface of the cam so that the right-hand prong is presented to the wedge-shaped end of the armature lever controlled by the single magnet M. If the magnet M is in the operated position the forked rod is diverted to the left, where it slides down the left-hand side of a fixed knife-edge E which holds it deflected until it is finally raised to the normal position again. When the tee lever encounters the second (raised) surface "b" of cam C_1 it forces rod FR still further downwards until a horizontal arm A encounters the lug L of a combination disc CD and displaces this slightly. If the magnet had been in the unoperated position (as shown in the diagram) the forked rod would have been shifted to the right side of E, and, when its downward motion was completed by cam surface "b" of C_1, A would be clear of CD and would have no effect on this. The forked rod has thus two directions of movement, being capable of one or the other according to whether the electromagnet enters into or does not enter into a letter signal combination.

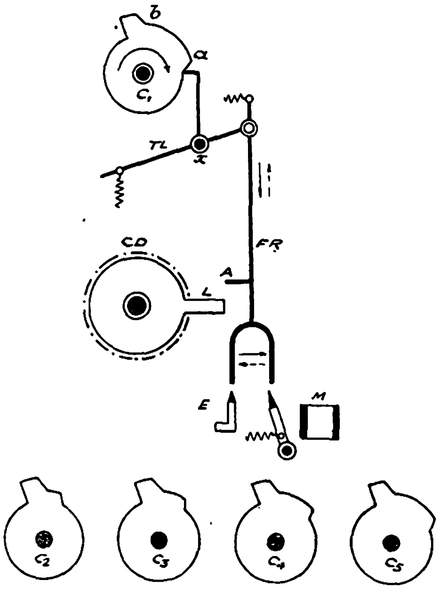

FIG. 86.—Baudot's single-magnet printer.

It is to be understood that there are 5 tee levers TL and 5 forked rods FR, and the knife-edge E and top of the armature of the magnet M can act on all of these. The remaining 4 cams are shown in the lower part of the diagram. It will be noted that the raised surfaces "a" come into operation in succession as the camshaft rotation proceeds, but that the second surfaces "b" all operate at once, the setting process consisting of a preliminary and a final stage.

A little earlier Baudot had invented and described another single-magnet method for translating the 5-unit code into typescript. This idea is extremely interesting on account of its similarity to some of the translators which have subsequently appeared. He describes it as a "mechanical distributor" and it uses one magnet only to set 5 selectors, as in the previous case.

C [Fig. 87(*a*)] is one of 5 cams angularly displaced with respect to each other and mounted on a rotating shaft which is stopped and started for each letter signal. Each cam controls a bell-crank BC, the lower end of which carries a selector bar S pivoted to it and friction-tight to such an extent that considerable force is required to move it round its pivot. The electromagnet is of the Hughes type in which the armature is repelled when a current passes through the magnet coil and is subsequently replaced mechanically. It has an armature A pivoted to the framework and a second one A_1 connected to the first by a link L. As the cam C rotates, the lower end of the bell-crank and with it the bar S is presented to the two armatures. If the magnet is not operated, the upper end of S abuts against the upper armature A_1 and turns on its pivot in a counter-clockwise direction. If the magnet is operated, the lower armature abuts against the lower end of S and the rotation is clockwise, A_1 having moved out of the path of the upper end of S. S is used either to close contacts mounted on BC, or, as Baudot suggests, it may be caused to hit or miss a combination bar CB.

Sacco and Giacomini's Distributor.—Fig. 87(*b*) represents in principle another mechanical distributor invented in 1891 by Sacco and Giacomini. Here a selector bar SB is given two kinds of motion, an angular motion over a number of combination bars CB and a reciprocating motion along its length. It is pivoted to an oscillating bar OB which is moved to the right when a marking signal pulse is received, but is stationary for spacing pulses. The selector bar is carried round past the ends of the combination bars CB by a disc D on a rotating shaft carrying a pin P which engages SB. If at the time SB is opposite a given combination bar a marking pulse is received, OB is rocked in a direction to cause SB to push the bar to the right. This will be recognized as the principle on which the setting of the combination discs in the Creed printer is based.

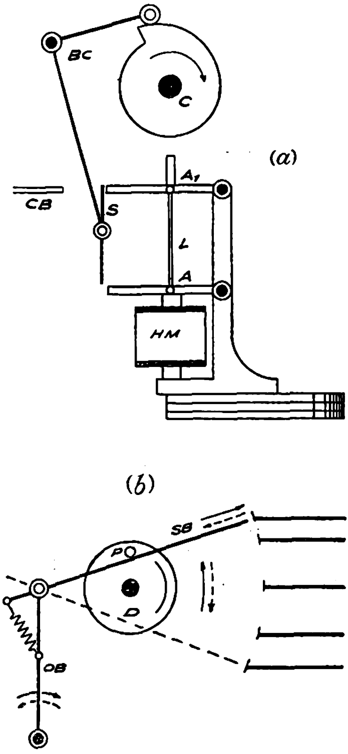

Fig. 87.—Baudot's and Sacco and Giacomini's mechanical distributors.

Morkrum-Baudot Printer.—In each of the methods previously described the setting of the combination bars is accomplished by power, the single magnet merely determining the selection. Fig. 88(*a*) is an arrangement due to the Morkrum Co., in which a rotating arm A sweeps over a field of pins P arranged in a circle. A is mounted on a sleeve S rotating on a shaft but free to slide on it to and from the circular plate in which the pins P are slidingly fixed. If the magnet M is inoperative during the entire revolution, none of the pins are disturbed, but if the magnet M is excited while A is passing over a pin, the sleeve S moves the arm A towards the pin through the medium of the fork F, and the pin is displaced. In this case the magnet has to do the work of setting, though this can be made very small.

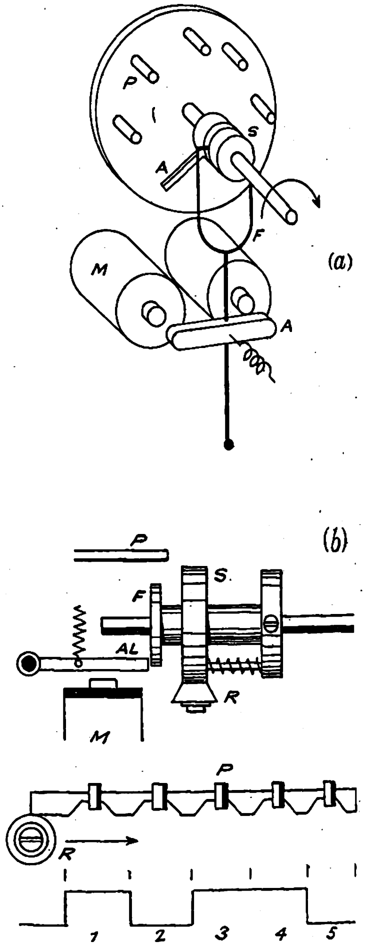

Fig. 88.—Morkrum's single-magnet selector mechanisms.

Another method introduced by the Morkrum Co. and actually used in their "Teletype" is shown in Fig. 88(*b*). S is a sliding sleeve which rotates with the shaft and on the periphery of which is a roller R. The sleeve is pressed to the left by a spring between it and a collar locked on the shaft. The armature of the magnet M restrains the motion of S as long as M is inoperative, by forming an abutment for the flange F. If, during any part of the revolution, M is operated, AL clears the flange F, and the sleeve moves to the left, setting any pin P which may be opposite to it. The pressure of F on AL is removed midway between the 5 pins by means of a circular disc (shown developed), so that the armature is free to move up or down to determine the setting of the pins. This relief is effected by the circular disc, the raised portions between the pins taking the thrust of the roller R. The changes from spacing to marking and vice versa will occur at about mid-distance.

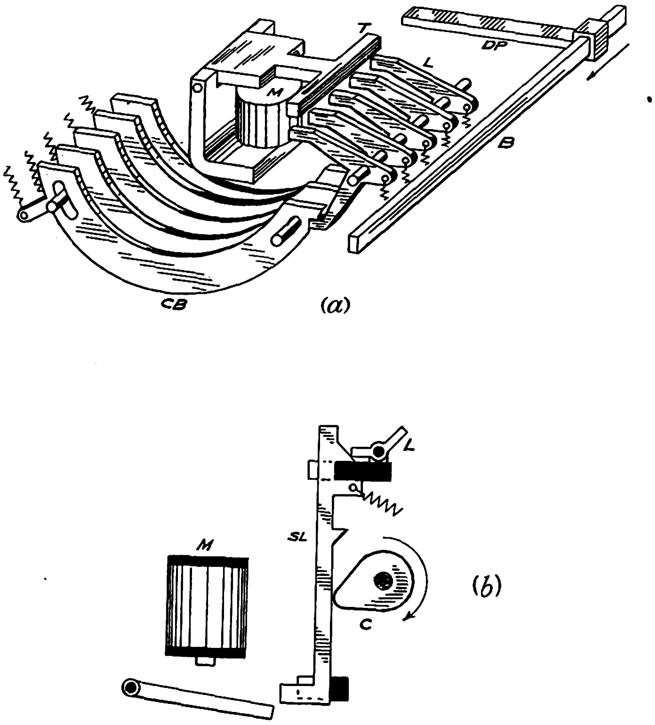

FIG. 89.—Murray and Potts's single-magnet selector mechanisms.

Murray's Single-Magnet Printer.—Fig. 89(*a*) is a scheme of Murray's based on the Sacco-Giacomini principle. Five quadrantal bars CB are held in their normal position by a series of latches L against the tension of individual springs. A single magnet M has an armature T tee-shaped at its free end and so disposed that in the operative position it does not affect the position of the latches. If, however, a distance piece DP is interposed between the nose of a latch and the tee-shaped extremity of T, the corresponding latch L is depressed and frees its combination bar. DP is traversed in the direction of the arrow across the noses of the latches.

Potts's Printer.—Fig. 89(*b*) is an arrangement due to Potts. Here a selector lever SL is slidably mounted at its upper end on a comb against which it is held by a spring. Its lower end is threaded through a second comb in which it is free to move to the left. There are, of course, 5 such levers and a group of 5 staggered cams such as C. If M is inoperative the cam C acting on the toothed cam surface on SL forces the lower end out in passing, the upper comb acting as the fulcrum. If the magnet is in the operative position, SL fulcrums on the armature lever and the upper end of SL is forced to the left and locked there by the small latch L. This is only a preliminary setting, as further selector mechanism is brought into engagement with those selector levers which have been set, the combination is transferred to the printer mechanism, and the latches L are operated to release the bars SL which have been set and allow them to return to normal for the next letter.

Kleinschmidt's Single-Magnet Distributor.—An ingenious form of mechanical distributor by Kleinschmidt is diagrammatically indicated in Fig. 90. Mounted on a horizontal shaft is a pin barrel PB having 5 angularly displaced pins P so arranged that when making a single revolution their circular path lies between a series of latches L. The shaft is driven by a sleeve S and by means of a friction clutch (not shown). The armature lever AL of a normally operated magnet M holds the shaft to the right against the action of a spring, seen in the upper part of the diagram. In this position a stop pin SP is caught by a stop lug SL and the shaft is stationary. If the magnet M is momentarily de-energized the shaft moves towards M, thus freeing SP from SL, and the shaft then makes one revolution until SP is again caught by SL. The pins P are allowed to come into the path of the setting lugs on the latches L each time M is de-energized, and by varying the number of times M is inoperative during the single revolution the latches L will be variably displaced counter-clockwise and made to release a set of combination bars (not shown).

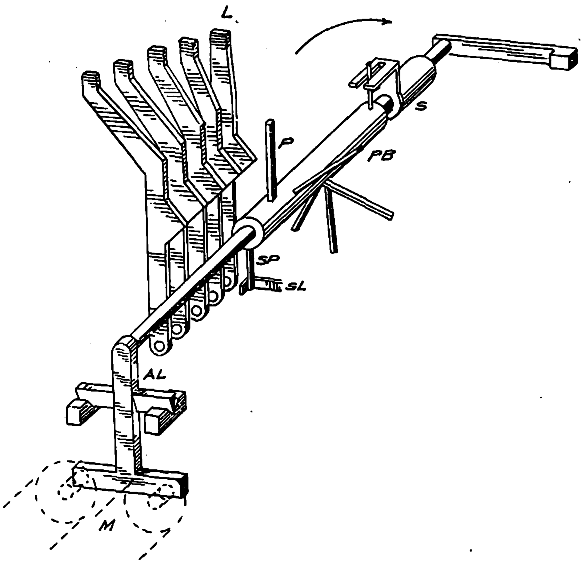

FIG. 90.—Kleinschmidt's single-magnet selector mechanism.

Interfering and Non-interfering Selectors.—An examination of the various types of mechanical distributor or selector will show that these fall into one of two divisions. The interfering type is one in which a camshaft operates a group of selecting elements in succession and when a marking condition prevails (marking signal element) the armature of the single magnet interferes with the movement of the selectors [Fig. 91(*a*)]. In the non-interfering type, the selector members move only when a marking signal pulse is received [Fig. 91(*b*)].

The selector mechanism applied by the Morkrum Co. to their type-bar Teletype is an improved form of the Baudot single-magnet selector mechanism shown in Fig. 87. The armature lever AL (Fig. 92) has a tee-shaped end, the two extremities of the horizontal portion of which are bent downwards and constitute two universal bars. This arrangement replaces the two coupled levers of Baudot's arrangement and is an improvement. The selector lever SL is also tee-shaped and pivoted in the free extremity of a bell-crank BC controlled by the cam C. There are 5 cams C acting in succession on 5 bell-cranks such as BC, each with its selector lever SL. The operation of this device is identical with that of Baudot. The selector levers, after being set and moved by the cam away from the armature lever AL, encounter a small tee lever "t" and move this to displace a code bar, as will be obvious from the sketch.

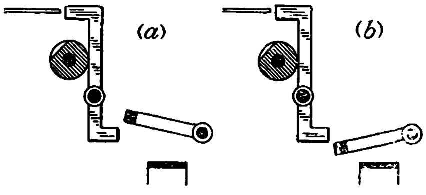

FIG. 91.—Interfering and non-interfering single-magnet selectors.

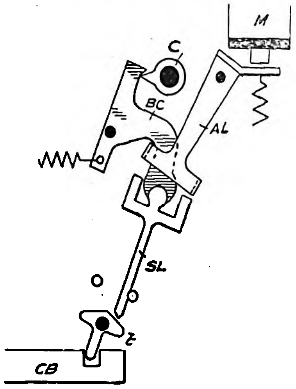

FIG. 92.—Morkrum single-magnet selector mechanism.

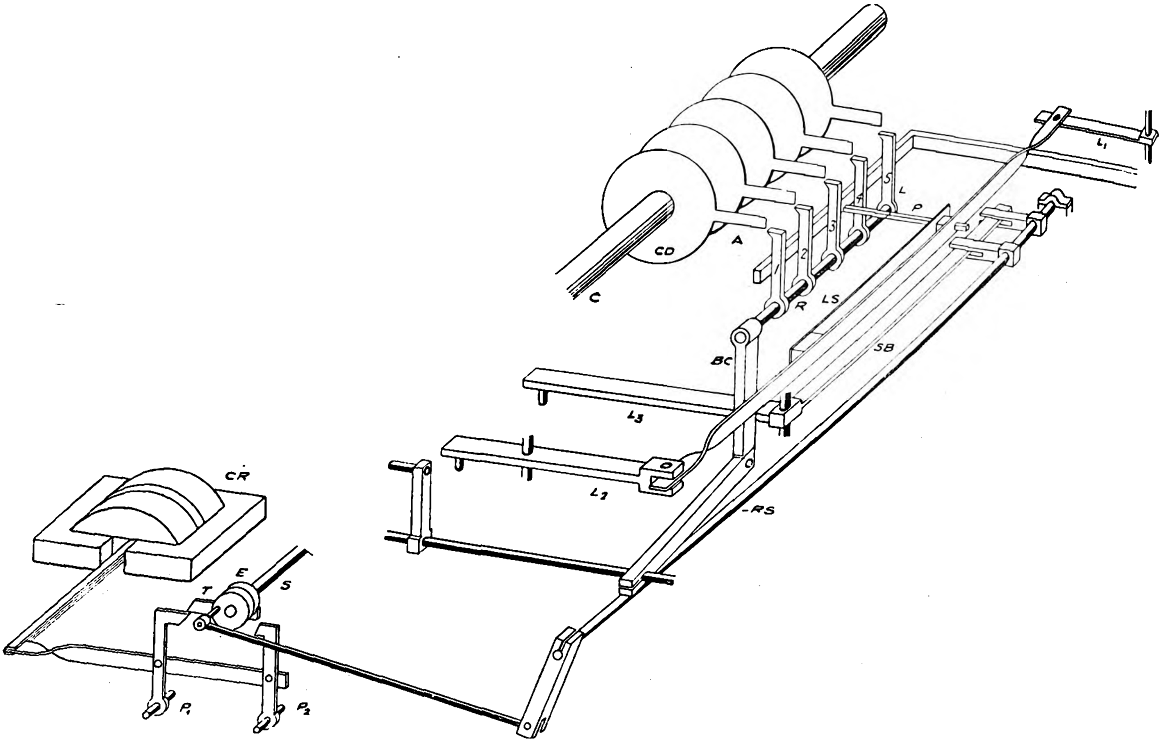

FIG. 93.—Creed's single-magnet selector mechanism.

Creed Teleprinter.—Fig. 93 represents diagrammatically the method of setting the combiner discs of the Creed teleprinter. The five discs are revolvably mounted on a cylinder C and have horizontal arms A for effecting their slight angular displacement. Their movement is accomplished by a set of 5 disc-setting latches L pivotally mounted on the horizontal rod R attached to a bell-crank BC, and adapted to be rocked at the right instant by a bell-crank CB so that those which have been pushed underneath the horizontal shifting arms of the combination discs will displace these. The latches L are set by means of a pin P which explores them in succession as it is moved in a horizontal direction by means of pivoted links L_1 and L_2. L_2 is controlled by a cam and the cam groove is so shaped that P is normally opposite the third latch but is carried to the first, then past the 5 and finally brought back to the third. In the normal position P is held away from the latches by means of a leaf spring LS but is moved against all or any by a spring blade SB oscillated by a lever L_3 controlled by a suitable cam. SB is supported in two forked slides rigidly attached to a rock shaft RS which can be so moved that SB is either in or out of the plane of P. The spring blade is moved towards the pin P 5 times while the latter is travelling over the 5 latches, and a marking pulse tilts the striker blade into the path of the pin while a spacing current removes it. Selection of the latches can thus only occur on receipt of a marking pulse while a letter signal is being received. The starting pulse is positive or marking and the letter signal pulses variably positive and negative, while the stop signal is negative. The control of the selector mechanism under control of the line signals is effected in the following way.

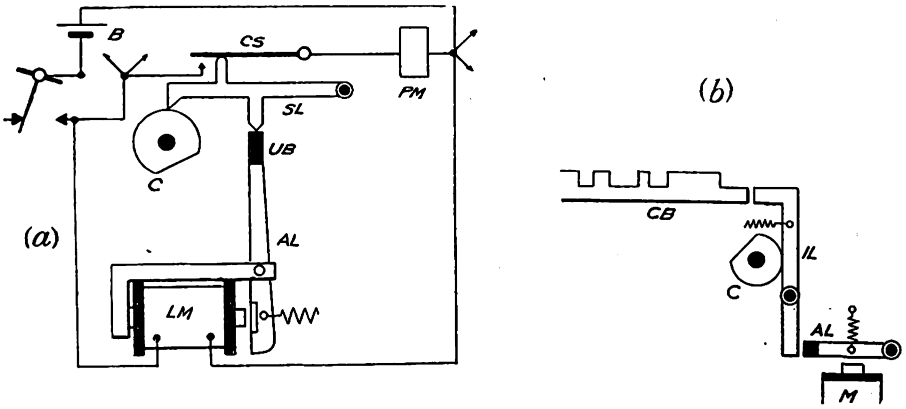

FIG. 94.—Comparison of electro-mechanical and mechanical selectors.

CR is a power relay of the Creed type which is either directly in the line or in a local circuit of a line relay. It controls an escapement mechanism consisting of two pallets P_1 and P_2 which allow a yieldingly-driven shaft S to make half a revolution each time the line current changes sign. The shaft is terminated by a single tooth T which is alternately caught by the pallets P_1 and P_2. The escapement drives a small eccentric E which rocks the shaft RS and affects the selective action of spring blade SB on P. The rock shaft also controls a single-revolution clutch which drives the battery of cams operating the different levers. This is not shown.

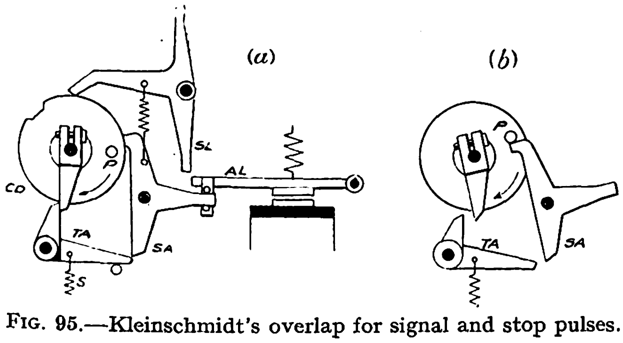

FIG. 95.—Kleinschmidt's overlap for signal and stop pulses.

The advantages of the " mechanical distributor " for single-channel working can be clearly realized by reference to Fig. 94. Fig. 94(*a*) is a single-magnet distributor in which, however, the selector levers variably close the circuits of five magnets PM to effect the setting of combination bars (not shown). Fig. 94(*b*) shows the simplification effected by causing the selector levers to act directly on the combination bars, thereby dispensing with five magnets and a similar number of contacts.

Overlap of Signal and Stop Pulses.—In mechanical start-stop selectors, the receiving mechanism is operated at a faster rate than the transmitting mechanism, so that the receiver will be stopped at the end of each revolution of the transmitter. If the impulses making up the whole letter signal are uniform in length, difficulty is experienced with the stop mechanism at high speeds. This is due to the fact that the time in which the receiving magnet and stop device must act is progressively shortened. The reduction of time for operating the stop reaches a dangerous limit; Kleinschmidt overcomes this by arranging for the stop pulse to overlap the last signal pulse of a letter signal. Referring to Fig. 95(*a*), SL is one of 5 selector levers controlled jointly by 5 cam discs CD and the armature lever AL of a single magnet. In the normal inoperative condition, the magnet is energized and holds a stop arm SA against the tail piece of a trip arm TA which, in turn, engages a stop clamped

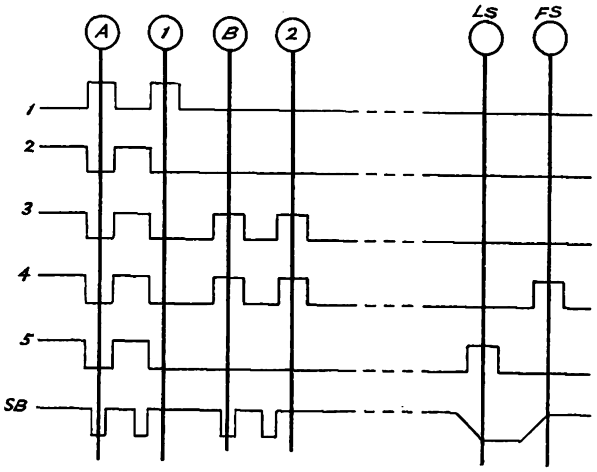

FIG. 96.—Inversion device for code bars or discs.

to the shaft on which the discs CD are mounted. The shaft is yieldingly driven through a friction clutch. When the magnet de-energizes in response to a start pulse, SA is removed from the tail piece of TA which is now no longer able to restrain the shaft from rotating, as the torque due to the friction clutch can overcome the weak spring " s."

If the last signal pulse is such that the magnet is de-energized, the head of stop arm SA comes in contact with a pin P and effects a preliminary stop of the shaft and cams, and on receipt of the final stop pulse the magnet depresses SA, which will lock TA in the stop position. If the last signal pulse had been a marking one, then, since the stop pulse is also marking, SA would have locked TA in the stop position before stoppage actually occurs. Thus, whether the last signal pulse is marking or spacing, the stop condition is set up at this stage and the stop condition overlaps the last signal pulse. This permits greater speeds of operation and finer speed differences and results in better margin.

Inversion.—Inversion or change from letters to figures is accomplished by axial or radial shift of the type wheel on its shaft in the case of a type-wheel printer, or shifting the type basket or platen of a type-bar printer. Both involve some amount of energy to accomplish and this can be avoided by using an extra bar or disc by which the primary and secondary characters may be selected at will by sending the appropriate signal. This is the arrangement used in the Creed printer and was first introduced into the art by the French engineer Munier in 1870. The principle is shown in Fig. 96. The primary and secondary characters are arranged alternately, on the type face of the wheel in the one case and adjacent type bars in the other. A sixth bar SB for shifting purposes has two sets of notches and two positions. In the position shown, the notches in SB allow only primary characters to be selected for any combination of bars 1 to 5. If bar 4 is shifted in response to the figure-shift signal, lever FS falls and shifts SB to the right. The notches under all the letter-signal type bars are now replaced by teeth and can no longer be selected, while the second group of notches is now shifted to a position which will allow only secondary characters to be selected. The return to the primary characters is obtained by setting combination bar 5, when LS will drop and shift SB to the position shown in the drawing.

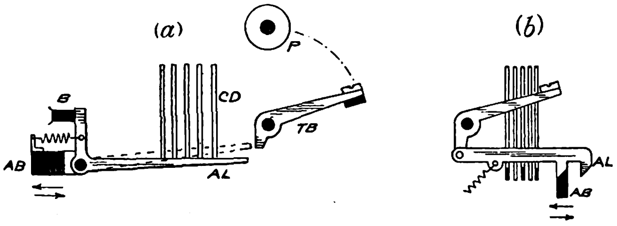

FIG. 97.—Murray's constructions for curved code bars.

Curved Code Bars.—Some simplification in design of type-bar printers with respect to the actuation of the type bars can be secured by using the curved code bars invented by Eglin. The code bars are of the same radius as the bar on which the type bars are hinged. Two constructions due to Murray are shown in Fig. 97(*a* and *b*). In (*a*) a number of actuating levers AL, one for each type bar, are pivoted to a curved actuator bar AB. Levers AL are normally held away from the curved code bars or discs CD by a curved bar B fixed to the frame. When the letter-signal combination is set up on discs CD, AB is moved to the right. All the levers AL leave bar B and one of them has an aligned slot presented to it, rises to the dotted position and engages the type bar TB as AB continues its movement.

In Fig. 97(*b*) the actuator levers AL are inside the code bars and as AB moves to the right the selected lever AL falls into the alined slot, its toothed end is engaged by AB and the type bar is actuated. The upper surface of AB is sloped so that on its return stroke it lifts the selected lever AL out of the line of slots in the code discs.

Curved code bars were independently invented by Murray and the Morkrum Co. in ignorance of their anticipation by Eglin.

Section (4). RECENT IMPROVEMENTS TO THE BAUDOT SYSTEM.

Improvements on the Baudot system have been directed to increasing its usefulness and reducing the work of maintaining a Baudot circuit in satisfactory operation.

Murray's Modifications.—Among the first-mentioned class may be quoted Murray's application of the phonic-wheel drive to the distributor drive. This resulted in much steadier speeds and dispensed with the skilled adjustment required by the Baudot governor hitherto used. There is still a certain amount of adjustment required to keep the reed or fork operating correctly, but such adjustment is of relatively simple character.

Murray also replaced the 5-key keyboard by a perforator and automatic transmitter, thereby dispensing with the necessity for the observation of the cadence signal and leaving the keyboard absolutely free. The substitution of a free for a bound keyboard should, theoretically, result in a higher operator output. The actual rate of transmission over the line is fixed by the distributor speed, and with a free keyboard and storage means, such as is furnished by a perforator-transmitter combination, the rate of setting up signals will normally exceed the rate of transmission. This allows for pauses in setting up without the lost time being transferred to the line, which thus works at constant maximum speed.

In this arrangement of Murray's the tape passes directly from perforator to transmitter, forming a loop the length of which depends upon the difference between the set-up and transmission rates. On a prolonged pause, the loop shortens and actuates a lever, thereby stopping the transmitter which, if allowed to proceed, would ultimately mutilate the tape. The general principle of automatic stop and start introduced by Murray is now in universal use.

Duplex Operation.—A further modification to the original Baudot system is the application of the duplex balance to the line. This has been extensively introduced in the British Post Office under Mr. A. C. Booth and is also in general use in America and elsewhere.

France, the home of the Baudot system, does not rely to any extent on the duplex balance for 2-way working but obtains this by simple division of line time. They have ample wire plant for their telegraph needs and prefer the greater stability of simplex operation which obtains both at terminals and repeater stations.

Duplex operation dispenses with the necessity of propagation contacts, but the same thing may be effected by the use of two lines. The capacity of a duplexed line is only $1\frac{1}{3}$ times its simplex operating speed as a maximum. This arises from imperfections of balance due to the fact that the charge and discharge quantities at the sending end of a line differ from one another and also that both the quantities and their difference vary with line leakage. The standard balancing networks ignore these facts and it does not seem possible to devise a network which can be rapidly and accurately adjusted to simulate the line with sufficient approximation to yield a double traffic capacity when operated under duplex conditions. With the increasing co-ordination of telephone and telegraph line plant which will result in making available an enormous number of telegraph channels, far in excess of traffic needs, both-way operation by the use of two lines—one for each direction—will probably become standard practice.

W	—2 3—5	1——4—	

(c)

FIG. 98.—Booth-Willmot keyboard perforator.

The duplex balance merely gives 2-way operation over a line at reduced traffic-carrying capacity.

Booth-Willmot Keyboard Perforator for Baudot Circuits.—One of the difficulties in applying the so-called " universal " keyboard to Baudot circuits lies in the different assignments of letters and figures in the two cases. This difficulty has been very ingeniously overcome by Messrs. Booth and Willmot of the British Post Office and the method is illustrated by Fig. 98(*a*, *b* and *c*) as applied to a Western Electric keyboard perforator. Five combination bars CB differentially notched are in the form of T levers and supported by two parallel links L_1, L_2 pivoted in a sliding carriage C supported on two rods R so that it is capable of moving backwards and forwards in a horizontal direction. The carriage can be moved to either position by means of bell-cranks actuated by the figure and letter keys FK, LK, respectively. The bell-cranks operate on pins fixed on the carriage, and the latter is held in either of its two positions by a jockey roller JR. With the carriage in one position one group of notches in the bars CB confronts the whole of the key levers, and in the other position the first group of notches is removed and replaced by a second group. When a key lever is actuated it selects the bars that are opposite to it *and unnotched* and presses these down. The left-hand extremities of the bars press on 5 or less of a number of bell-cranks BC which withdraw the punch selectors PS so that, when the punch hammer PH is operated, only those punches whose selectors have not been withdrawn are forced through the paper strip. If the carriage C is shifted to the other position, then a different punch selection is set up for the operation of the same key lever.

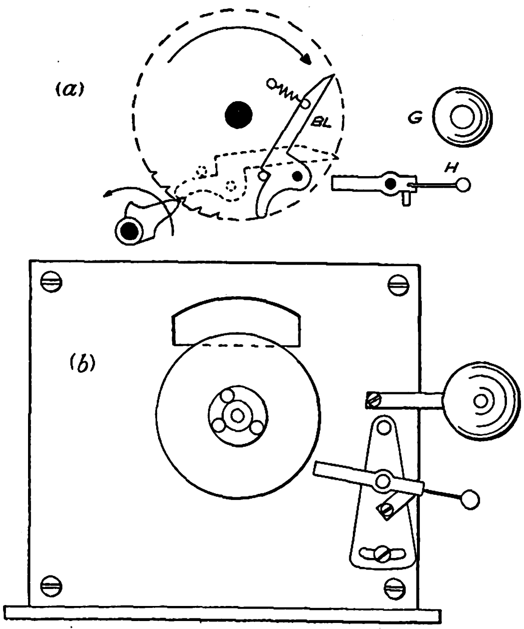

FIG. 99.—Bell-ringing arrangement on Baudot printer.

In Fig. 98(*b*), with the bars CB in the position shown the operation of key lever KL will operate bars 1, 3, 4 and 5, but if the bars are shifted to the left by the amount *d*, only bar 1 will be operated when KL is depressed. In this way the assignment of letters and figures on the keyboard can be as desired without interfering with the standard assignment on the Baudot type wheel. This is very important where a Baudot keyboard may be employed at one end of a circuit and a " universal " keyboard at the other. It will be seen that selection of the punches to form any desired letter is attained by withdrawing the punch selectors of those punches which are not required to form the letter or figure corresponding to the actuated key lever. This leads to a very interesting result. A frequent form of "stumble" when operating a keyboard at high speed is to depress two adjacent keys simultaneously. In the ordinary way this would lead to the perforation of a wrong letter. The punches common to the two letters would operate and, in addition, those not common would be effective. Back-spacing and obliteration of the wrong letter, and the re-punching of the letter required, would be carried out in the standard manner, but line time is lost by the transmission of the obliteration signal—5 punched holes—succeeded by the correct letter. Thus the error costs an amount of line time equal to one letter—the obliteration signal. When, however, the unwanted punches are made ineffective, only those common to the two letters are operated. This is clearly shown by Fig. 98(*c*), where the depression of key Q withdraws punch 2 and the depression of key W withdraws punches 1 and 4, the resultant effect on the tape being the punched holes 3 and 5. Since 3 and 5 enter into the signal combination for both Q and W, then whichever is the desired letter will be correctly punched by back-spacing once and operating the desired key. There is no necessity for the obliteration signal, and one letter signal's length of line time is very simply and ingeniously saved.

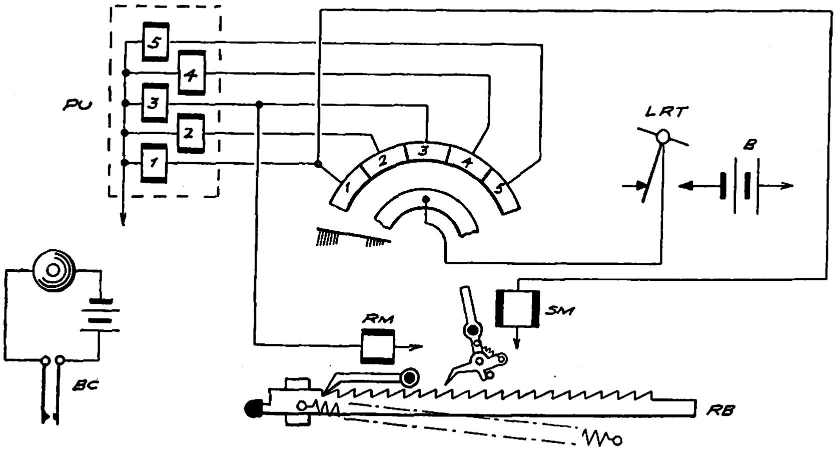

FIG. 100.—Selective calling arrangement for series Baudot circuits.

New Zealand Administration's Bell-Ringing Arrangements.—The provision of a single-stroke bell on a printer mechanism is becoming general practice. The bell is usually selected by sending a shift signal and is rung once per cycle of printer operation. Code ringing may be adopted to furnish service instructions such as "Stop," "Re-run," etc., and as an indication to the transmitting operator it is superior to code signals set up on the printer itself. The mechanism for applying bell signalling to a Baudot printer, as designed by this Administration, is shown in Fig. 99. To the impression disc behind the type wheel a lever BL is pivoted and is held in the normal position shown against a stop by means of a spiral spring. After the receipt of the figure shift signal and in the succeeding revolution, the impression arm is released by the secondary character following letter A, and the impression arm turns BL on its pivot so that its free end projects beyond the impression disc and strikes the hammer H, ringing the bell once. The bell can be rung one or more times in succession (once per revolution) and bell strokes can be suppressed for one or more revolutions, thus forming a signalling code. Fig. 99(*b*) shows the general arrangement. This method requires the printers to be continuously revolving.

Fig. 100 shows a method of selectively ringing idle arms at a number of stations on one line and is useful where Press items have to be distributed. RB is a rack bar stepped forward, one tooth at a time, by a stepping magnet SM against the control action of a spiral spring. It is returned to normal when the release magnet is operated, which occurs when a "third" is sent. The stepping is shown as being effected on receipt of a "first." The rack at another station would be stepped on receipt of a "second," and so on, but all return to normal on receipt of a "third." Normally the printer is at rest, but the distributors are running at all the stations on the line. When all arms are carrying traffic the bars at each station are intermittently stepped, but as "thirds" are constantly occurring the bars are continually becoming re-set to normal. As stated, this arrangement is specially designed for Press work and any number of stations may be rung to receive a certain news item, while those stations not rung will ignore it and will not start up their printers on that arm.

With this arrangement a number of stations provided with double, triple or quadruple distributors can be strung in series on one line wire and, with no traffic passing, the distributors only will be kept running. Any station can be selectively called on any arm, the whole arrangement being thus made suitable for news working.

Grünenwald Speed and Phase Control of Printer Units.—The two to four printers on a Baudot circuit are ordinarily driven by independent motors, speed control being effected by a modification of the Baudot governor. Approximate synchronism is secured by the arrangement shown in Fig. 91 of the author's previous paper.[*] The necessary phase relationship between the printer cycle and the distributor cycle is secured by orientating

[*] *Loc. cit.*

the synchronizing means on the printer unit. This arrangement entails two to four individual adjustments and although these are relatively permanent they must be verified from time to time, and, if a change in operating speed is called for, readjustments are necessary.

The ideal arrangement is one in which distributor speed and printer speed and phase is accomplished by one adjustment, viz. variation of distributor speed. This can be secured by providing synchronous motors on each printer unit and furnishing alternating current from the distributor.

Fig. 101 illustrates the electrical arrangements. The four printer motors have stators S_1 to S_4 furnished with alternating current generated from direct current passed through a series of reversing commutators C_1 to C_8.

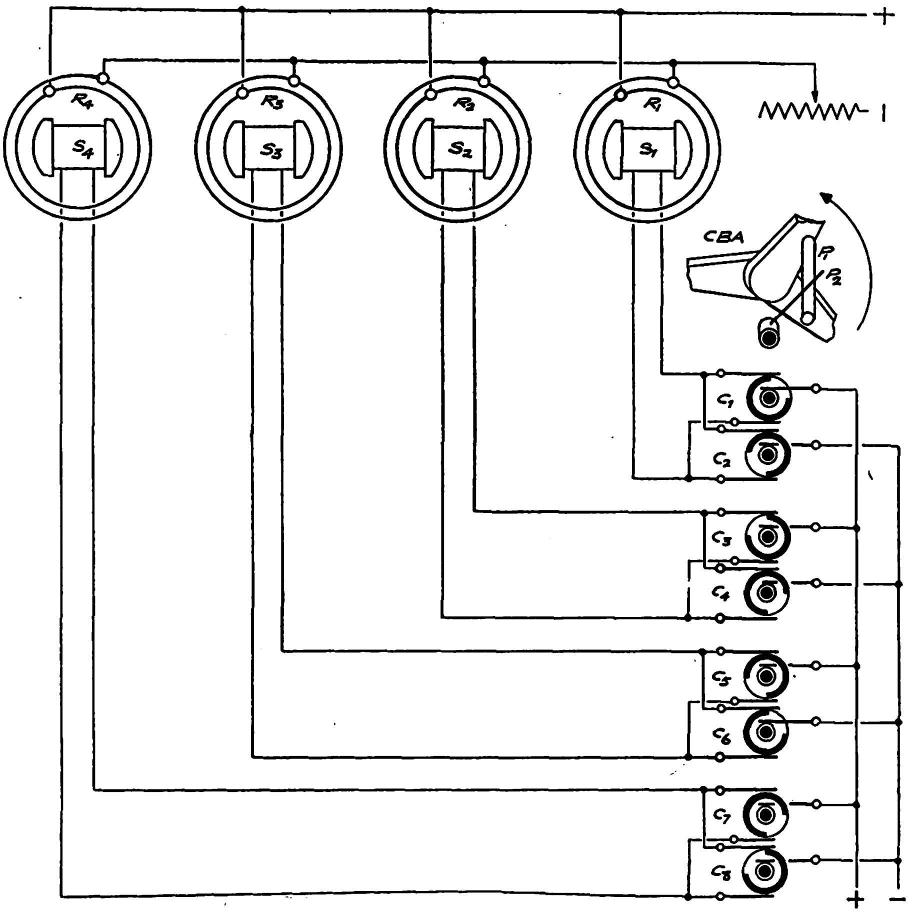

FIG. 101.—Grünenwald's automatic speed and phase control of printer units.

The rotors R_1 to R_4 consist of a heavy flywheel on which is mounted a toroidal coil, the two ends of whose windings are connected to slip-rings and excited from a d.c. supply through a regulating resistance.

The reversing commutators are suitably displaced with respect to each other, so that each printer has the correct phase relationship with respect to its distributor segments. They are mounted on a common shaft and insulated from each other and this shaft is driven by a pin engaging a second pin P_2 on the contact brush carriage CBA. This method of drive is necessitated by the fact that, at a corrected station, the phase of the brushes is intermittently varied and the phase of the printers must therefore be simultaneously varied, otherwise a phase error will creep in. Also, the orientation of the segments is variable in amount and it is not possible to drive the printers from fixed segments on the distributor itself.

The adoption of the Grünenwald printer drive effects simplification in the printer itself. The low-speed synchronous motors drive directly on to the type-wheel shaft and all gearing is suppressed. Owing to this it is possible to arrange the keyboard in the printer base instead of making it a separate unit, and this modification is illustrated by Fig. 102. The synchronous motor SM is housed at the back of the printer unit and covered in by a bell-shaped casting. The keyboard is instantly removable from the base by simply pressing down bolt B, when it can be pulled out together with the whole of its mechanism and electrical contacts. It is mounted on a sliding shelf. The method of locking and unlocking the key-levers KL will be understood from Fig. 102 and the sketch below. Each key is held in the normal, unoperated position by the spring S_1 anchored to the shelf on which the keys are mounted.

A cam C is provided on the type-wheel shaft and this depresses an unlocking rod once per revolution, the slight clicking noise forming a cadence signal for the operator. This rod ULR operates a small piston mounted in a circular recess in the printer base, and an extension to the piston presses on a cam plate CP adjustably fixed to an unlocking lever UL fixed on a shaft S passing right across the keyboard shelf and housed in two bearings integral with this. A coiled spring (not shown) tends to keep the rod in a horizontal position and keeps the piston in such a position that the rod ULR is pressed at its upper end against the cam C.

When a key is depressed, a steel plate at its free end is caught by a latch L loose on the main shaft and pressed forward by a spring S_2. The release of all keys so locked up is effected as previously described.

Fig. 102 also shows the arrangement of a keyboard independent of the printer. An electromagnet CM performs the unlocking function and acts to give an audible cadence signal.

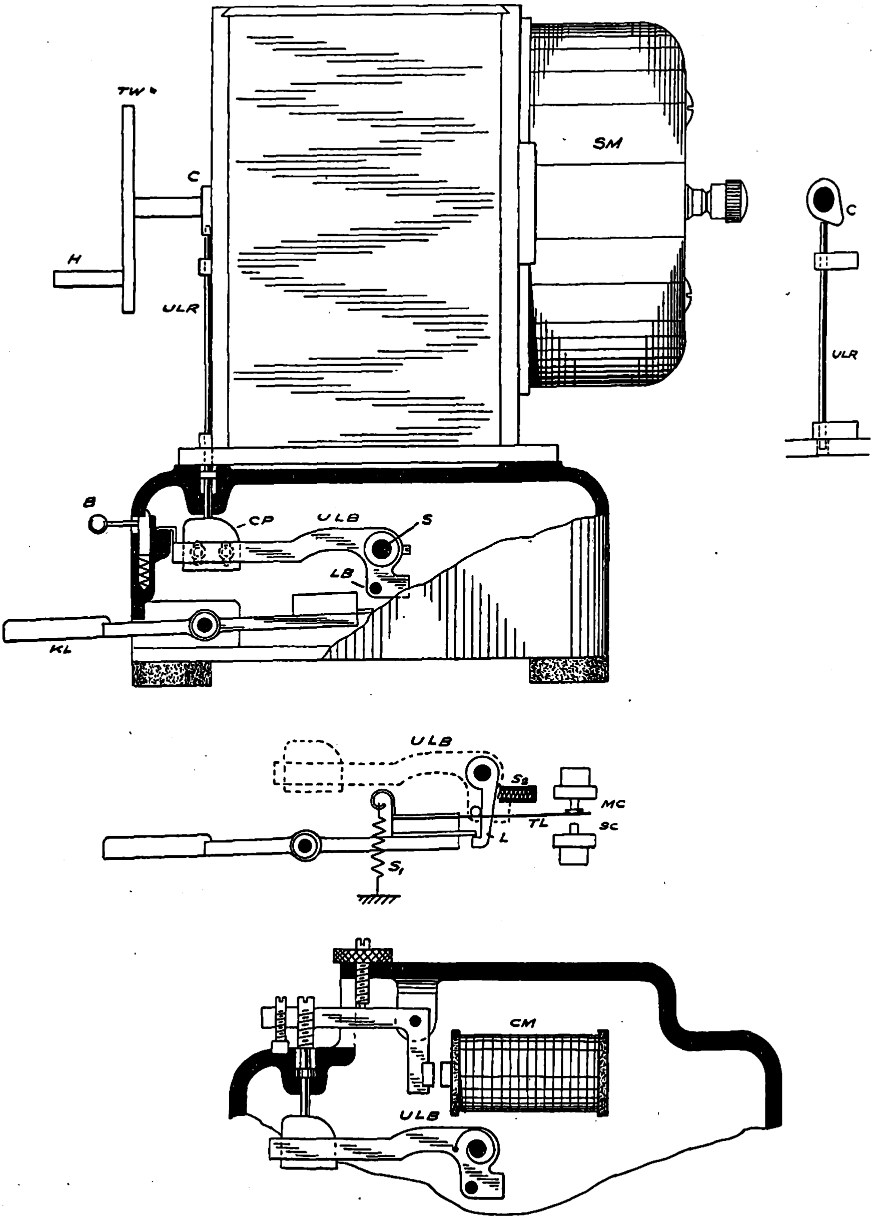

FIG. 102.—Grünenwald's modifications to Baudot printer.

Verdan-Baudot Anti-parasitic Device.—This arrangement is specially designed to deal with the Baudot apparatus when applied to a radio link and subject to atmospheric disturbances. The presence of atmospherics superposed on Baudot signals results in wrong letters being printed, and at times of bad disturbance an almost unreadable slip is produced.

The principle on which the arrangement is based is the following:—If the same letter is transmitted two or three times, separated by a certain interval, the actual signal elements will be absolutely regular, but atmospheric disturbances will be irregularly distributed over the total time. The effect of atmospherics will be to reinforce the desired signal elements and to add others. Under the conditions outlined, probability calculations show that there are a considerable number of chances that the atmospherics will not appear invariably at the same instants of time as the signal elements.

If the signal elements are repeated at intervals of time greater than the average duration of an atmospheric disturbance, they will not introduce the same " extras " at each transmission. By the adoption of a storage device at both sending and receiving ends arranged to repeat the letter signals at intervals of time corresponding to six revolutions of the distributor brush arm, the correct letter is finally passed to the printer. In Table 1 the " sifting " process at the receiving end is set out.

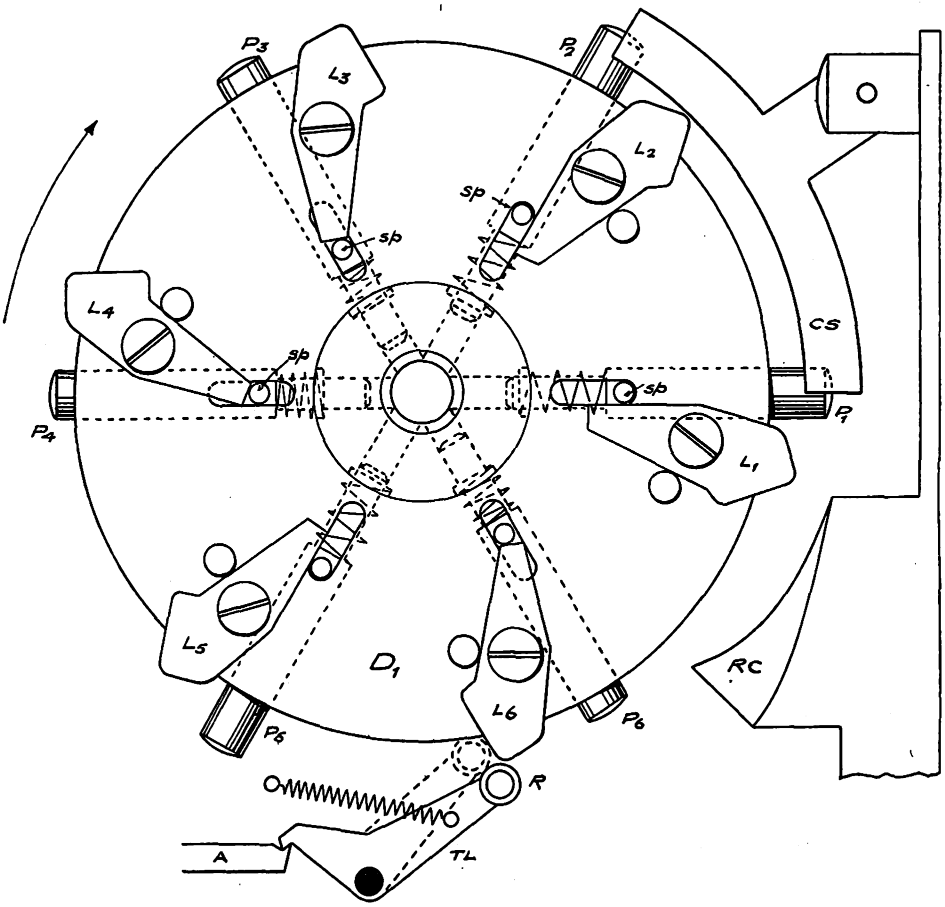

FIG. 103.—Verdan's storage transmitter.

In the table the letter Y is supposed to be sent (spacing current on segments 1, 2, 4 and 5 and marking current on segment 3). Atmospherics are shown by the crosses ×.

If we connect the five magnets of a Baudot retransmitter to the distributor sector, then magnets 2, 3 and 4 will be operated, setting armature levers 2, 3 and 4 to the operating position. If the working contacts of the retransmitter levers are connected to the magnets of a second retransmitter and the magnets of the first retransmitter disconnected from the distributor sector, while six revolutions later the retransmitter levers of the first apparatus are connected to the distributor, then the magnets of the second retransmitter will receive the first repetition of the letter signal via the transmitter levers of the first retransmitter and the distributor sector. At the second repetition the second retransmitter magnets are switched on to the distributor and extend the receiving circuit to the printer magnets.

TABLE 1.

Distributor revolutions	Signals					Letters		
	1	2	3	4	5	Sent	Received	Stored
1st		×	+	×		Y	F	F
7th	×	×	+		×	Y	V	I
13th			+	×	×	Y	R	Y

In Table 1, magnets 2, 3 and 4 are first operated and at the seventh revolution only the corresponding magnets of the second retransmitter are connected up. Consequently, atmospherics 1 and 5 are without effect and only atmospheric 2 and signal pulse 3 operate magnets 2 and 3 of retransmitter No. 2. At the thirteenth revolution, only printer magnets 2 and 3 are connected up (there is no atmospheric this time on segment 2), while atmospherics 4 and 5 cannot have any effect as the corresponding printer magnets are not connected. Only pulse 3, the correct signal pulse, is therefore recorded, the storage arrangements having sifted out the unwanted signals.

In practice, a 3-sector or triple distributor is used and the letter signal is switched on to these in turn. This makes it possible for the operator to set up other letters between the first transmission and subsequent repetitions of the same letter. The storage mechanism (of which there are two) is driven independently of, but in synchronism with, the distributor.

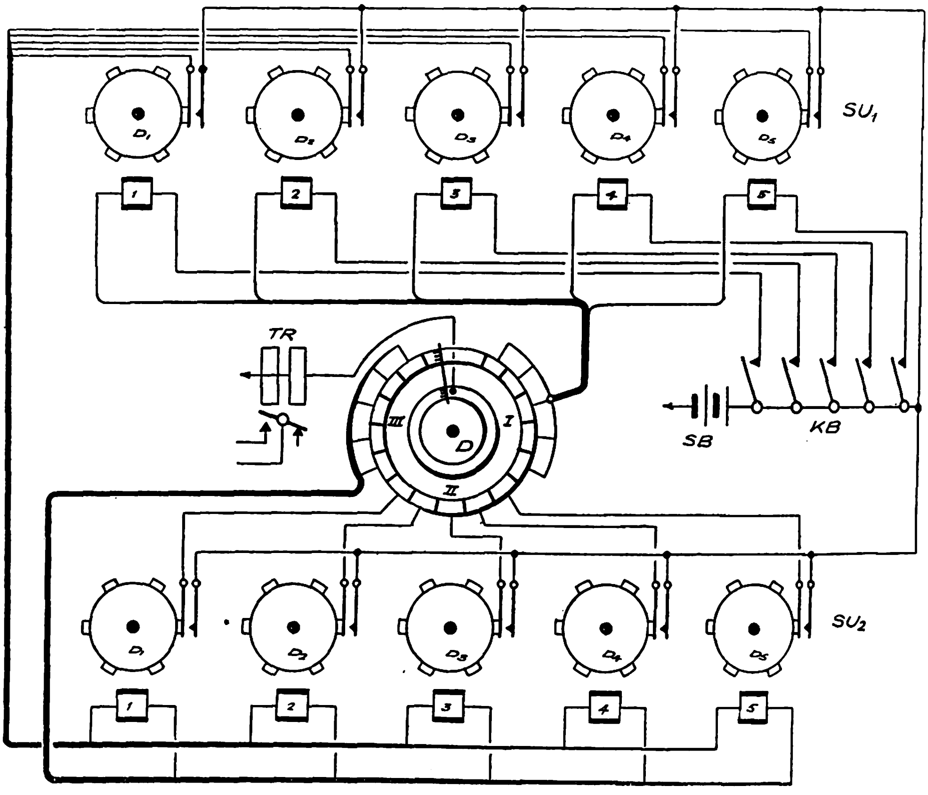

FIG. 104.—Verdan's anti-parasitic transmitter.

Referring to Fig. 103, each storage unit consists of five discs D_1 to D_5, each containing six radially disposed plungers P_1 to P_6. The plungers are pressed outwards by spiral springs surrounding their lower ends, but are normally held inwards by stop pins projecting through slots in the discs and held by latches L_1 to L_6. The latches are pivoted to the discs as shown. Adjacent to the lower portion of each disc is a setting magnet (not shown) the armature of which holds a spring-controlled trip lever TL, the free end of which carries a roller R. If the magnet is energized TL moves to the dotted-line position and as a latch comes round it is forced round in a counter-clockwise direction to release the stop pin of the plunger, and latch and plunger assume the positions shown at P_5. Five of such discs with their magnets provide for the storage of six Baudot letters.

When the displaced pin has passed beyond the vertical position, it enters between two contact springs CS, and completes a circuit for the next stage ahead. Pins which are not displaced clear the contact springs and have no effect so far as the next stage is concerned.

RC is a resetting cam which restores the plungers to normal in readiness for the receipt of another letter.

The transmitting arrangements are shown in Fig. 104. D is a triple distributor and SU_1 and SU_2 the two storage units. KB is the operator's keyboard, on which letters are set up in succession in accordance with the cadence signals. The two storage units are on a common shaft and rotate at a speed one-sixth that of the distributor.

When a letter is set up on the keyboard, the circuits of some of the five storage magnets are closed successively in series with the segments of sector I of the distributor D, solid ring of same, transmitting relay TR to earth at the sending battery SB. The letter signal is sent out to line and simultaneously stored in the storage unit SU_1. Six revolutions later, the displaced pins in SU_1 close circuits for the corresponding magnets of storage unit SU_2 in series with sector III of the distributor and relay TR. The letter signal is again sent to line and stored in the second storage unit, while the letter is cleared from the first storage unit by the resetting cam.

After a further six revolutions of the distributor, the second storage unit repeats it to line via sector II of the distributor, and the reset cam clears the second storage unit of this particular letter. The letter signal has now been sent out three times at intervals of six revolutions (2 seconds) during which time six other letters have also been sent out.

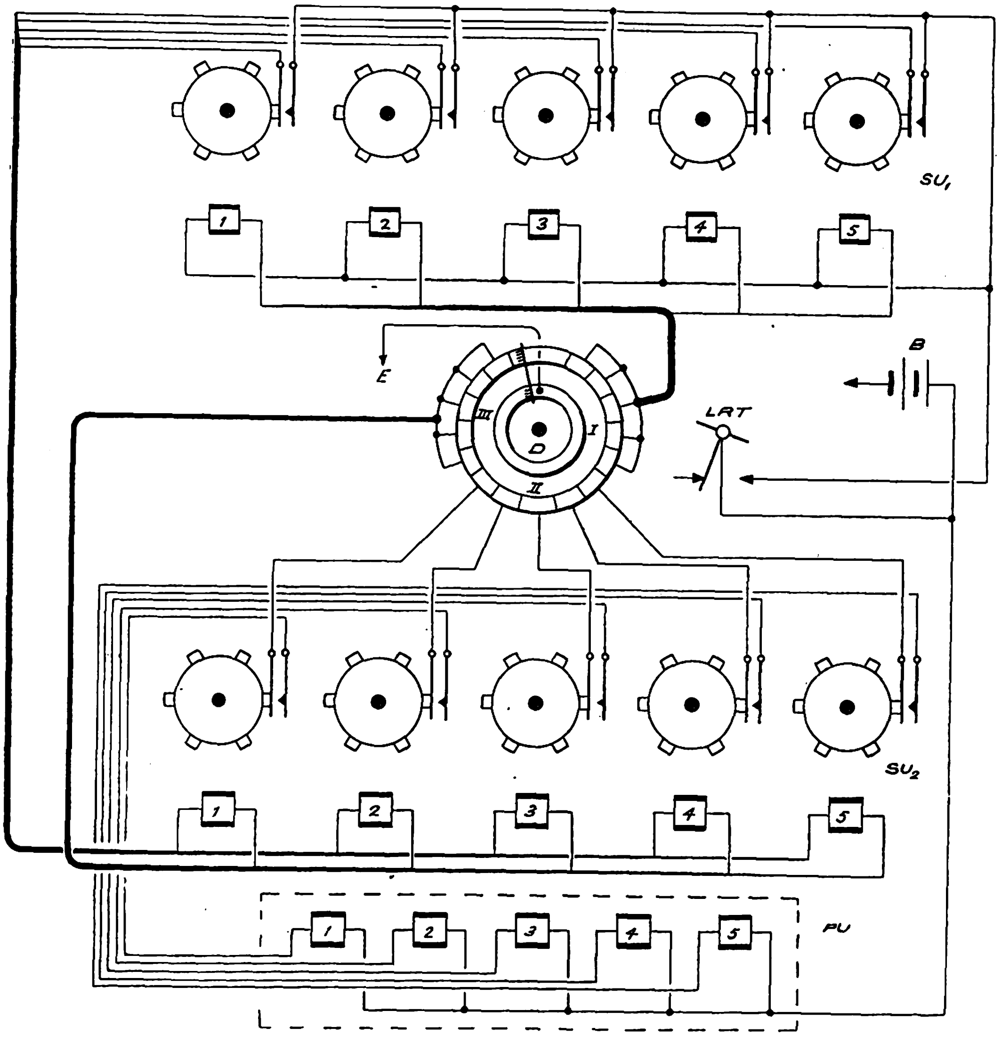

FIG. 105.—Verdan's anti-parasitic receiver.

TABLE 2.

Transmission	Revolutions of brush arm																
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
1st sector 1	T	E	L	E	G	R	A	P	H								
2nd sector 3	·	·	·	·	·	·	T	E	L	E	G	R	A	P	H		
Confirmation sector 2 ..	·	·	·	·	·	·	·	·	·	·	·	·	T	E	L	E	G

At the receiving end (Fig. 105) the arrangements are similar to those at the transmitter. Two storage units are employed and these are also on a common shaft and driven at one-sixth the distributor speed. The line relay controls by its tongue LRT the successive setting processes. The printer magnets of the printer unit PU are set on the third repetition of the letter signal from the relay tongue LRT via the contact springs of the second storage unit. The process in sending the word "Telegraph" is shown in Table 2.

Correction impulses are treated in the same way by an independent storage mechanism of relatively simple character.

This arrangement has been in successful operation between Paris and Algiers for some time. Paris transmits to Crois d'Hins (near Bordeaux) on a quadruple over an aerial line. At Croix d'Hins automatic retransmitters send the signals over a sextuple Baudot-Verdan arrangement which controls the radio transmitter. From 8 a.m. to 8 p.m., the most difficult 12 hours of the day from the radio point of view, a good service is assured. Two sectors with two repetitions are normally available, but at times of heavy traffic, and provided the atmospheric conditions permit of repeating only once, three sectors are available.

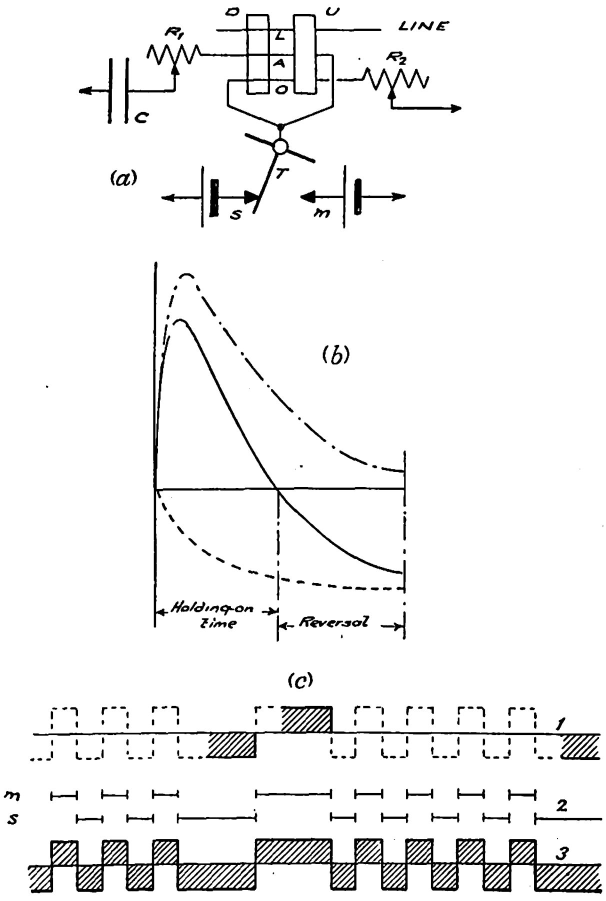

Fig. 106.—Gulstad relay operation.

The Baudot-Verdan arrangement gives an overall performance superior to other methods and, in addition, renders radio transmission absolutely secret.

Section (5). REGENERATIVE REPEATERS.

Gulstad Relay as Interpolator.—On long lines or cables the overall transmission speed can be raised by the insertion of suitable repeaters *en route*. The signals, especially those of higher frequency, are attenuated as they traverse the line circuit and attenuate at different rates, so that some do not survive when the receiving end is reached. Disturbances from neighbouring conductors will shorten or lengthen some of the signalling pulses, and the ordinary repeater, if inserted at a point where the attenuation of the higher-frequency pulses is below a certain limit, will repeat the signals as a fair copy of those imposed on the line by the originating transmitter. Such repeaters produce some measure of signal distortion themselves since no relay tongue is absolutely free from " bounce " when suddenly moved from one contact to the other and therefore does not at once make effective contact. Further, the transit time, although only a matter of 0·001 or 0·002 sec., is a fairly high percentage of the signal pulse time when the signalling frequency is high. The combined effect of " bounce " and transit time is to clip the repeated signals, which are thus not a faithful copy of the originals.

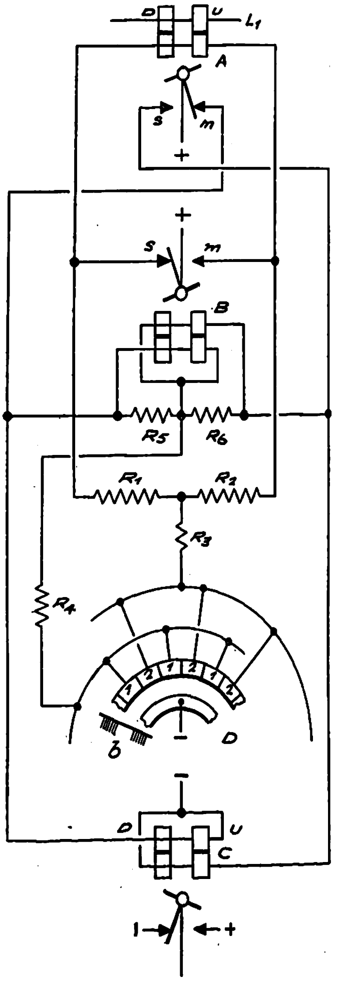

Fig. 107.—Synchronous Gulstad operation.

Both of these defects in ordinary relays are largely overcome by the system of operation invented by the late Oscar Kaye Gulstad, engineer-in-chief of the Great Northern Telegraph Co.

For cable working a special type of Gulstad relay is required, but for land-line operation the Gulstad method can be applied to any polarized telegraph relay. Briefly, it consists of a relay with three windings, a line winding and two others arranged to be opposite to each other in their effect on the relay cores. In Fig. 106(*a*) one winding, the accelerating winding, is shown in series with adjustable resistance R_1 and condenser C; while the other, the opposing winding, is in series with a resistance R_2. The coils are connected together at their other ends and to the relay tongue T. A split battery is joined to the marking and spacing stops M and S.

When T is on either contact and there is no current in the line winding L, the transient current in the accelerating coil exercises a "holding-on effect" which secures firm contact. Current in an opposite direction is building up in the opposing winding, and, as the transient holding-on current decreases, the opposing current reverses the armature as shown in Fig. 106(*b*) with appropriate values of R_1, R_2 and C; the relay, if left to itself, will steadily vibrate at a rate which can be made approximately equal to the rate of reversals from the distant transmitter. The current in the opposing winding must be less than the line current in order that pulses of longer duration than reversal pulses can take charge and stop the relay from vibrating. During the transit of the tongue from one contact to the other the condenser discharges through both windings A and O in a direction to accelerate the movement of the tongue and thus shorten the transit time. The Gulstad principle almost removes the two defects of the ordinary type of relay, but it does much more than this. Since the energy required to move the tongue from one contact to another is furnished locally, as is also the force necessary to ensure good contact pressure, the line current exercises a controlling function only and greater signal attenuation is permissible. This means that the length of a circuit may be extended without reducing speed, or, alternatively, that the speed may be increased on a line of given length. Thus in Fig. 106(*c*) the speed is such that the reversals do not get through, only the long negative or positive pulses surviving. Owing to the fact that the relay is made to vibrate at the reversal speed of the distant transmitter, the reversals are interpolated at the receiving end, while the line current exercises control and stops the relay vibrations for a dash or long space. Thus the relay repeats the signals from the distant end as an approximately correct copy of the originals. On any line the speed can be raised deliberately so that reversals do not get through, provided only that the longer pulses are sufficiently powerful to stop the vibration when required. The only other limit to this procedure is possible difficulty with the duplex balance at the sending end. In Fig. 106(*c*) instrument lag and transit time have been neglected.

Synchronous Gulstad Operation.—The Gulstad relay is most efficient when its vibrations are exactly synchronous. This adjustment is very difficult to attain and has given rise to a method of operation on long high-speed cables known as synchronous Gulstad working.

Briefly this method consists in the provision of a rotating distributor kept in synchronism with the distant station's transmitter. The local windings of the relay are then controlled from contacts on the synchronous distributor, and the relay, when not controlled by the line signals, vibrates in absolute synchronism without the necessity for skilled adjustment. One such arrangement is shown in Fig. 107. It comprises three relays, a line relay A, an auxiliary vibrating relay B and a repeating relay C together with a distributor D having a series of odd- and even-numbered pairs of segments for controlling relays A and B. Relay A is also subject to control from the line signals and it controls the operation of the repeating relay C. The distributor is maintained in synchronism by means not shown and the brushes "b" traverse one pair of segments (numbers 1 and 2) during the time of one half-reversal or cycle (one baud). When the brush "b" is on an odd-numbered segment, relay B is set by relay A, and when on an even-numbered segment relay B sets relay A. This reciprocal action is subject to A being free from line-signal control.

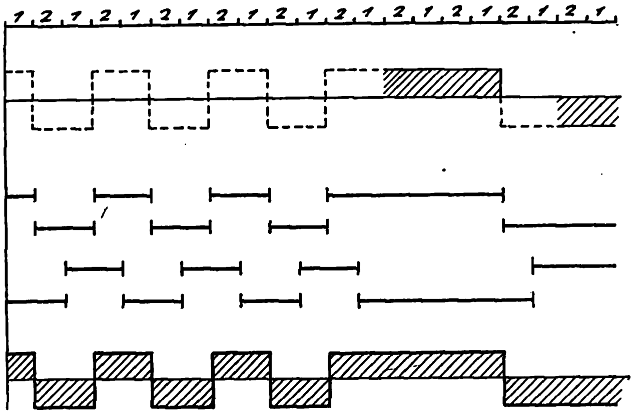

FIG. 108.—Current/time chart of operation of synchronous Gulstad relay.

The operation of the system is as follows:—With the brushes "b" on an odd-numbered segment and relay A at marking, relay B is thrown to spacing, the circuit being negative, marking contact and tongue of relay A, lower winding of relay B, R_4, segment 1 of D and solid ring via brushes "b" to negative. When the even-numbered segment 2 is bridged by brushes "b," a circuit is closed from positive spacing contact and tongue of relay B, lower winding of A, R_2, R_3, segment 2b and solid ring of D to negative. Each relay is thus set by the other half a cycle apart. Under these circumstances the repeating relay C is vibrated by relay A in exact conformity with the distant transmitters' reversals, due to the fact that D is running in synchronism.

The current/time chart in Fig. 108 shows the actual signals in the line, those shown dotted being the pulses which do not get through. The positions of the relay tongues (marking or spacing) of relays A and B are indicated below, while the original signals re-created and repeated and as sent out to line L_2 by relay C are given in the last line. This arrangement is due to the Bell Telephone Laboratories.

The arrangement shown in Fig. 109 is due to L. R. Foster, and has the peculiarity that the relays do not vibrate continuously when interpolating reversals, the advantage being that the contacts are not subject to wear from the continuous hammering as in other methods.

Four relays are required:—Relay A, the line relay, is of the 3-position type, relays B and C are ordinary polarized relays with three windings, two operating windings and one locking winding, while relay E repeats the signals to the next line section and has one operating and one locking winding.

D is a distributor running in synchronism with the distant transmitter as usual. It has two rings of segments bridged by a rotating brush " b." The upper ring of segments 1 is divided into two groups and alternately connected to the tongues of relays B and C. Each of these segments is swept over in the time of one half-reversal (baud). Opposite each of these segments is a pair of segments, the first of which is multipled to the corresponding segment of the other pairs and then connected to the operating winding of relay E. If line relay A receives a long positive or negative pulse it operates relays B and C so that they both pass to marking or spacing, the control being effected through their line windings connected to the tongue of relay A.

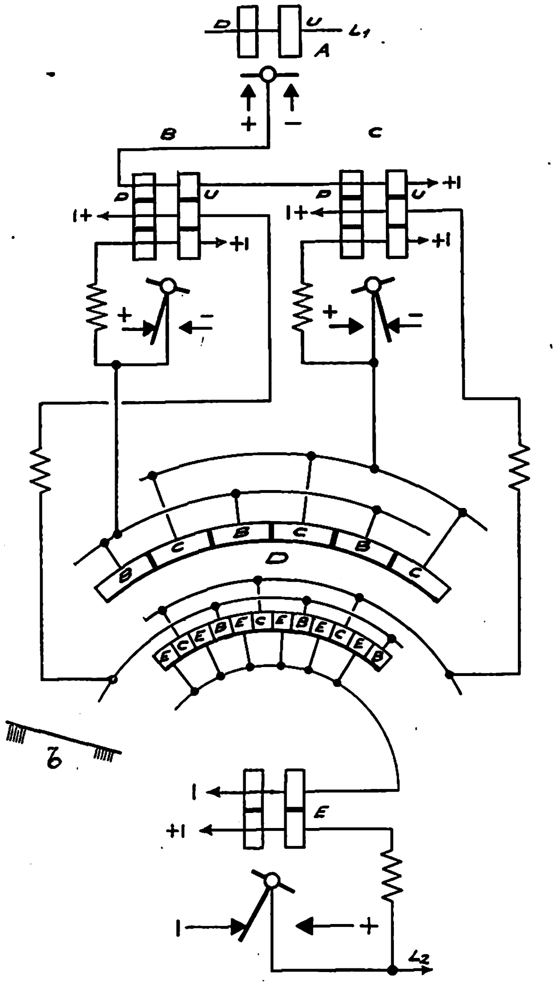

FIG. 109.—Synchronous Gulstad operation.

When brush B comes on a B segment it connects the tongue of relay B at first to the operating winding of relay E and then to the local operating winding of relay C. This current is able to overcome the locking winding current of C and if B is on its marking contact at this time C is operated to place its tongue on its marking current. The polarities of marking and spacing contacts of relays B and C are opposite to each other as shown. When a C segment is reached, relay C, which is now on its marking contact, closes a circuit from negative, segment C, half-segment E, reversing the position of relay E and later half-segment B, keeping relay B on its spacing contact. With no interference from line relay A, relays B and C retain the positions shown in the diagram, but relay E is regularly vibrated in synchronism with the distributor.

The current/time chart (Fig. 110) will explain the behaviour of the combination when actual signals are received. The top line shows the line signals as originated, the second line the signal pulses received and controlling relay A, the third line the positions assumed by the tongue of relay B, the fourth those of relay C and the fifth the current pulses sent out by relay E. Relay E is the real interpolator of missing dots, the distributor chopping up the continuous pulses of relays B and C.

Neither of these arrangements constitutes a regenerative repeater; they are interpolators only and the outgoing signals are still subject to slight distortion from bounce and transit time, although in this respect they are much superior to the ordinary type of repeater. Fig. 111 shows an interpolating repeater due to Heurtley and Foll. Incoming signals operate the line relay LR which controls a re-transmitting relay TR connected to the next section of the line L_2. A lever CL is operated by a rotary cam C mounted on a rotating shaft and synchronized to make one revolution for each signal pulse sent from the originating station. The closure of contact C_3 is arranged to take place at the mid-portion of a signal pulse, and only during this time is LR able to operate TR. The operation of the arrangement is set out in the chart below the diagram, the orientation of the lever CL being purposely shown incorrectly. When this adjustment is properly made the outgoing signals will be free from distortion and only clipped

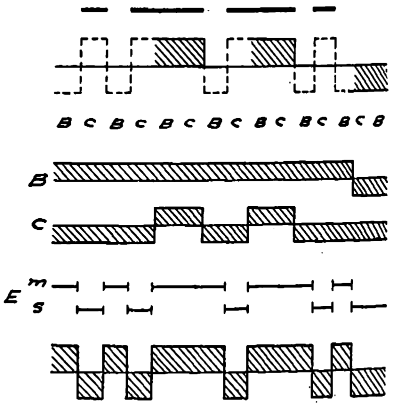

FIG. 110.—Current/time chart of synchronous Gulstad operation.

slightly by the effect of the transit time of relay TR.

True Regenerative Operation.—A truly regenerative type of repeater may be defined as one in which, at the initiation of a retransmitted signal, the repeating relay tongue has reached the desired contact, marking or spacing, and all bounce has subsided. There is thus a setting cycle preceding the transmitting cycle and these must not overlap. The received signal must therefore be effective for a length of time equal to twice that of a signal pulse, and the sending-on relay is set during the first half-period and retransmits during the second half-period. In this way the retransmitted signal is free from irregularities due to transit time, etc., and is an exact copy of the original. The regenerative repeater was invented by Baudot.

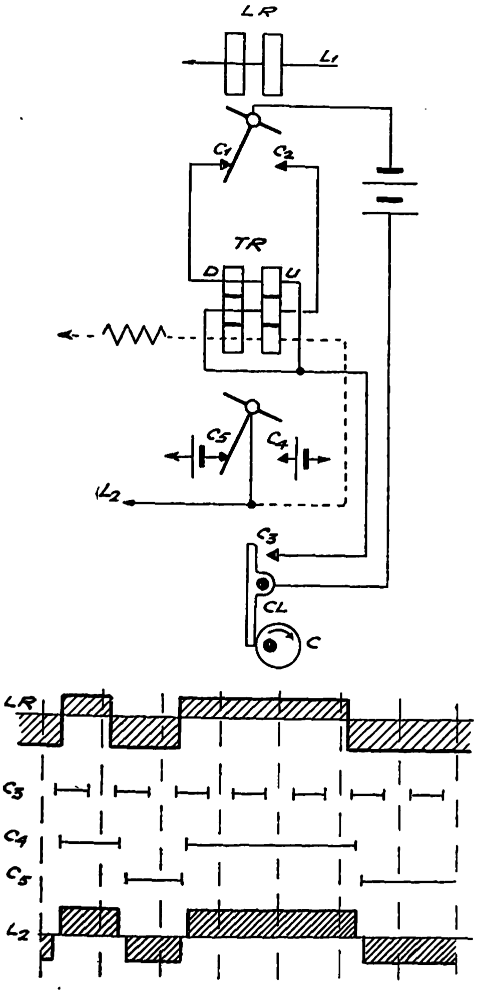

FIG. 111.—Heurtley and Foll's interpolator.

A typical regenerative repeater is shown in Fig. 112. It consists of a receiving line relay, LR, and two retransmitting relays A and B in combination with a synchronous distributor having a receiving face RF and a transmitting face TF. Incoming line signals from L are repeated by LR via the solid ring of RF, brushes "b," and shortened segments "a," "b," to relays A and B alternately. Relays A and B, when set, are held in position by a weak locking current. The brushes "b_1" and "b_2" sweep over the "a" segments simultaneously and in this way relay A is set on an "a" segment and transmits via the succeeding "b" segment on the transmitting face TF. The transmitting segments are full-length and the retransmitted signals are therefore of correct length also and start immediately the brush "b_2" commences to sweep over a segment. The current/time chart will make the operation of the arrangement quite clear. It will be noticed that the clipping effect on the received signals due to LR is entirely removed from the regenerated signal, and this is due to the fact that when either relay A or B is sending out a signal pulse it is already at rest firmly on its marking or spacing contact.

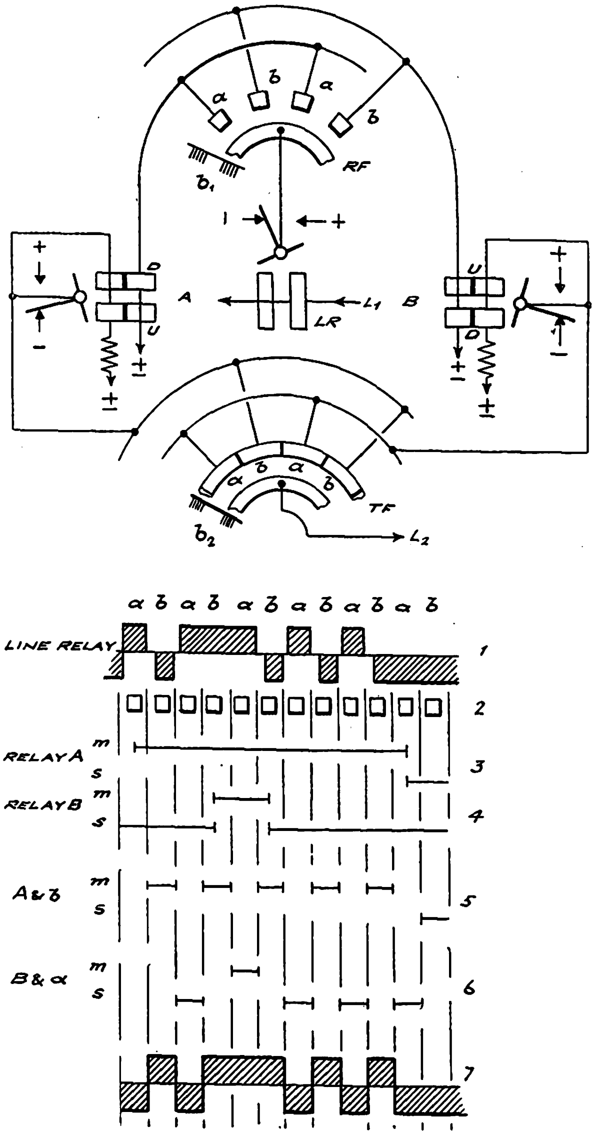

FIG. 112.—Principle of regenerative repeater.

The same arrangement can obviously be applied at the sending end, the transmitter taking the place of the tongue of line relay LR. In this way the transmitted signals are also rendered free from blemishes. This is now the general practice on long lines.

Eastern Telegraph Co.'s Regenerative System.—Fig. 113 represents diagrammatically the interpolator-regenerator used by the Eastern Telegraph Co. at an intermediate station forming one of a number of repeating points on a multi-section submarine cable. The incoming signals control a cable relay CR, the moving portion of which has a thin U-shaped contact-making member. The contact-making member has two antennæ which normally make contact with two pins mounted on a bridge piece of insulating material. The polarized relays PR_1, PR_2, are biased to their marking stops but are held to spacing by the local circuit of the cable relay CR.

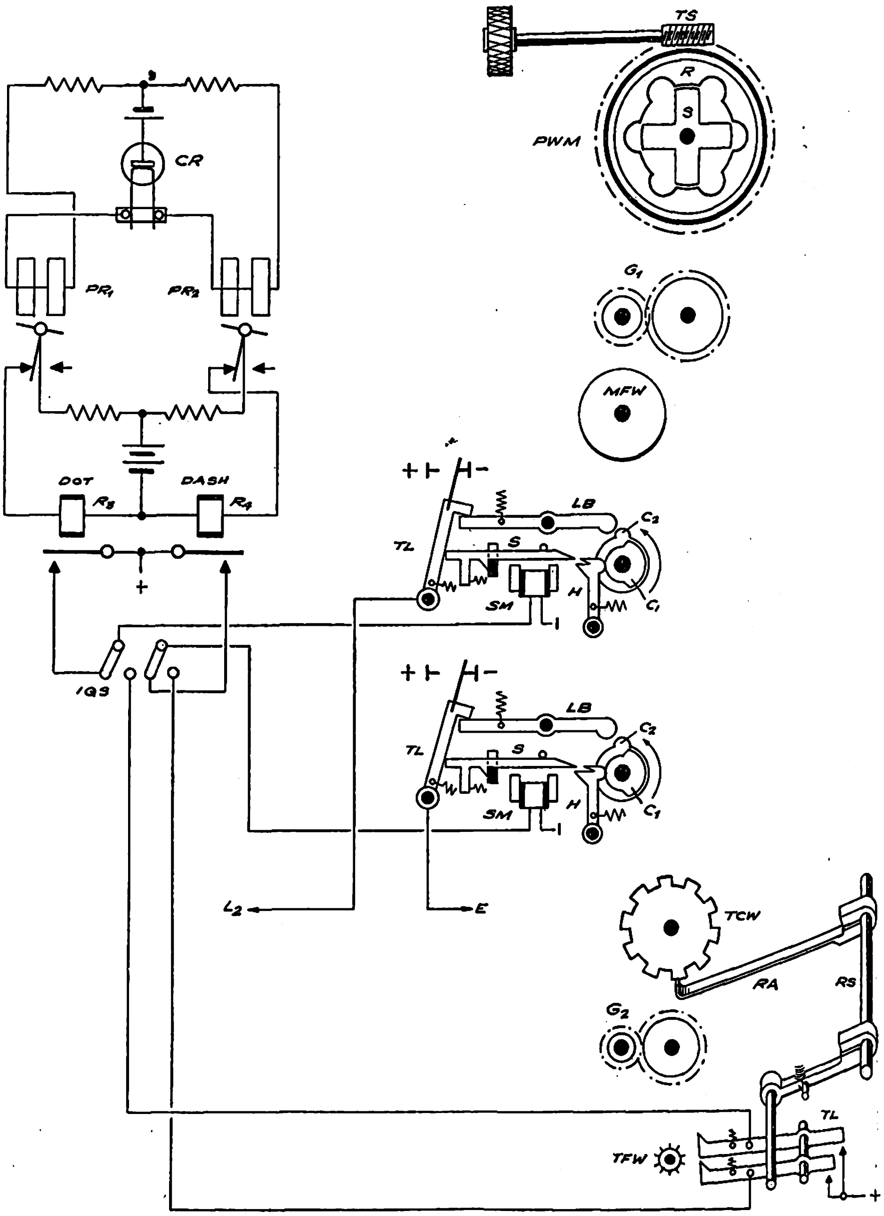

FIG. 113.—Eastern Telegraph Co.'s regenerative repeater.

If relay CR moves to right or left, one of the antennæ leaves its pin and the corresponding polarized relay is de-energized and proceeds to its marking stop by reason of the bias previously mentioned. The dot or dash relays, R_3, R_4, which are normally energized, are released by their corresponding polarized relay and close a circuit from positive through the switch IQS to the selector magnets SM of the interpolator. The interpolator mechanism consists of two transmitter levers TL, one for dots and the other for dashes.

PWM is a phonic-wheel motor driven at a speed equal to that of the motor driving the distant transmitter. PWM drives, through a step-up gear G_1, a secondary shaft on which is mounted a mercury flywheel MFW and two sets of cams C_1 and C_2. At the lower end of this shaft is a second set of gears driving a transmitter code wheel TCW which, by means of rocking arm RA mounted on rock-shaft RS, controls the oscillations of two transmitter levers TL forming the usual cable code transmitter. The transmitter operates continuously but is without effect as long as IQS is in the "through" position shown in the illustration. Dot or dash signals operate the selector magnets SM and depress the selector member S into the path of a hammer H. The latter is driven forward by cam C_1 and retains S in the operated position while pushing it to the left to reverse the position of the lever TL. When TL reaches the reverse position, latch-bar LB springs up and locks it. At the end of the signal period C_2 raises the right-hand end of LB, depressing the far end and releasing TL, which snaps back into the normal position (as shown).

Fig. 116.—French international regenerative repeater circuit.

The stator of the phonic-wheel motor can be displaced with respect to the rotor by means of the tangent screw TS. This enables the best part of the received signals (i.e. near the middle of a pulse where distortion due to bounce, etc., has vanished) to be selected. This orientation adjustment is effected by the passing of working signals, the stator being moved in one direction until the signals fail, then moved through the correct position in the contrary direction until failure again occurs. The middle of the two extreme adjustments is the correct position for S.

If the intermediate station has traffic for any other or for the terminal station, the IQ switch is turned to the right and the transmitter operated by perforated tape. It then controls the selector magnets of the interpolator mechanism and signals pass out to line L_2 in the standard manner. The perfect system of synchronism employed by the Eastern Telegraph Co. has been described previously.

Fig. 114 is a map of the cable route from London to Cape Town. Intermediate regenerator-repeaters are inserted at Porthcurnow, Fayal (Azores), St. Vincent, Ascension and St. Helena. At Cape Town the signals are recorded on a perforated tape and passed through a cable-code printer. This route commenced operating on the regenerator system on the 19th. January, 1927. Routes with as many as 11 relays are now in operation.

Signals have been transmitted from London to Penang (Straits Settlements) and back, employing 21 relays. Prior to the introduction of the regenerator no more than two relays of the then existing type could be employed.

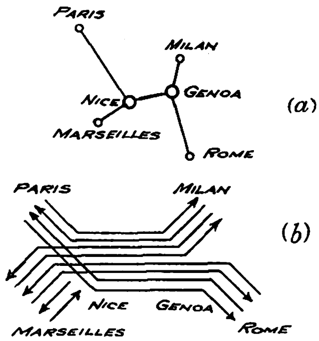

Fig. 117.—Line plant and channel arrangements of French international regenerative repeater circuit.

As a further example of the advantages of the regenerative repeater in building up long circuits, the circuit between San Francisco and London (Fig. 115) may be cited. There are 20 repeaters in circuit, 13 of the ordinary and 7 of the regenerative type. The length of the circuit is 7 400 miles, of which 2 600 miles consist of submarine cable.

Interworking of Circuits with Different Numbers of Channels.—When using the 5-unit code, a whole letter may be set up, stored and retransmitted at a later part of distributor revolution. This requires 5 relays per channel because the operation is not now pulse by pulse but letter by letter. All the advantages of regeneration are retained but the phase of the setting and retransmitting cycles may now be so adjusted as to permit of channels from 4 channel (quadruple) being worked through to 3 channel (triple) or two channel (double) or any of these types working through a duplex multi-channel system.

The utility of this is very clearly shown by Figs. 116 and 117. Here a quadruple at Paris has two channels to Milan and two to Rome. At Marseilles a sextuple furnishes two channels to Milan, two to Rome and two to Nice. The circuit between Nice and Genoa is furnished by a submarine cable worked on the quadruple-duplex-system.

Fig. 118 is the arrangement of the German-American cable worked at 250 words per minute by five channels of 50 words per minute each. A regenerative repeater is provided at the Azores. New York and Emden have one channel each to the Azores. Channels 2 and 3 are used by the Western Union Co. for Emden–New York traffic, and channels 4 and 5 are leased to the Commercial Cable Co. also for Emden–New York traffic. The British Post Office and Continental Administrations share channels of a single link in the same way.

Regenerative Repeaters Combined with Voice-frequency Transmission.—If to the principle of division of line time a plurality of voice frequencies are added as a further means of selection, channel repeating by regenerative repeaters may be considerably extended. Fig. 119 shows these combined features. London works to Paris quadruple-duplex, using d.c. transmission. Two duplex channels serve for London-Paris traffic, the other two being extended to Zurich. The number and arrangement of the channels are set out in the diagram.

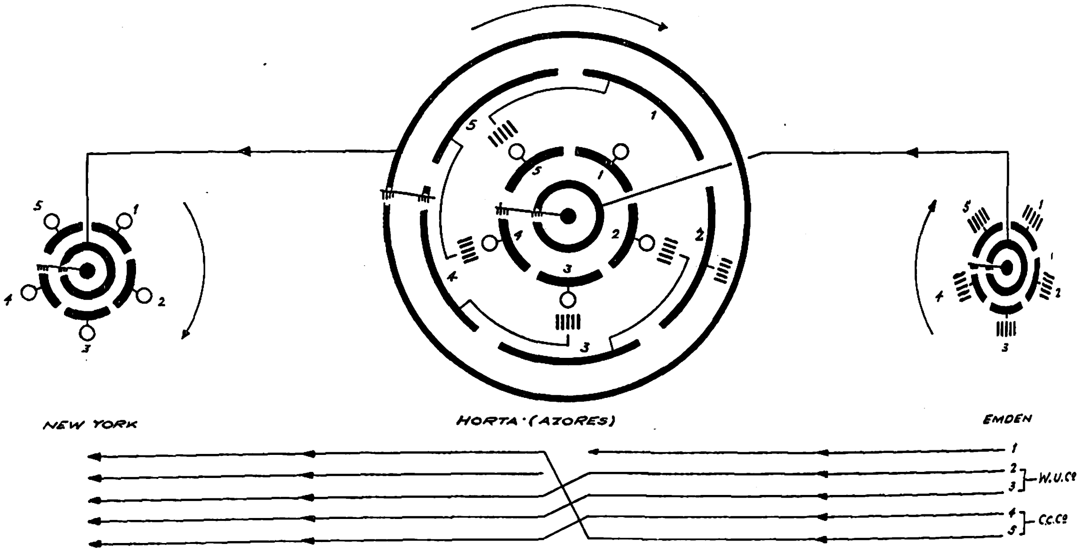

Fig. 118.—German–American regenerative repeater.

The a.c. voice-frequency signals pass through two repeater stations *en route*, these being of the standard telephone type, and the lines consist of two pairs in a telephone cable.

When the League of Nations is sitting at Geneva an additional frequency is employed, giving 8 or 4 duplex channels between Geneva and Paris.

Effects of Bias.—In the case of a long link with several regenerative repeaters at intermediate points, the accumulation of bias must be guarded against. Bias can arise from a variety of causes, such as inequalities of spacing and marking batteries, earth currents, defective relay or transmitter adjustments, and so on. Stoppages to locate the point at which the bias originates are costly, and hence careful scrutiny of the outgoing signals at all repeating points is necessary. Slow changes of phase due to inaccuracies in synchronism will produce the same effects as bias. The continuous operation of a long and costly circuit depends upon careful observations directed to the detection of tendencies harmful to accurate transmission, and the "automatic scrutineer," the invention of Mr. K. L. Wood and employed on the Eastern Telegraph cable system, detects a tendency to bias and draws attention to this.

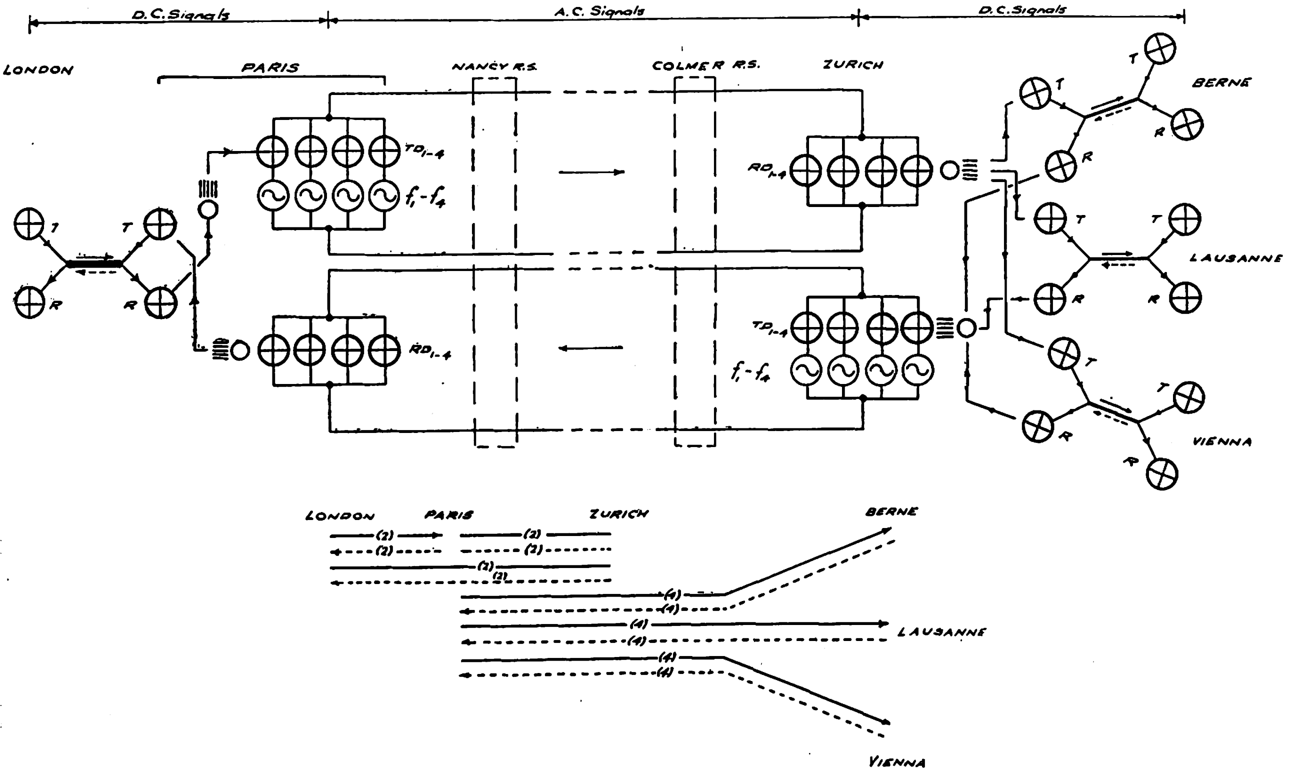

FIG. 119.—English–French international regenerative repeater arrangements.

Automatic Scrutineer.—Fig. 120(*a*) shows reversals with a spacing bias and the effect on the receiving relay is shown in Fig. 120 (*b*), where the marking pulses are seen to be shortened while the spacing pulses are lengthened. The points at which changes of sign take place are shifted to the right, changes from positive and negative being characterized by a smaller shift than those from negative to positive. Fig. 120(*c*) shows the same signals with a marking bias, and Fig. 120(*d*) represents the effect on the receiving relay. The effects here are exactly the opposite of those occurring in the previous case. The changes of sign are again shifted to the right but the greater shift takes place on a change from positive to negative. Fig. 120(*e*) shows the usual ring of shortened receiving segments, from which it will be seen that the maximum shifts are effected when the brushes are about to sweep over these segments. Even with this amount of distortion, signals will not fail and will be regenerated correctly, but the system is on the verge of failure and should have been readjusted before the conditions in (*b*) and (*d*) had been reached. Fig. 120(*f*) shows an arrangement by which the introduction of bias, however caused, is indicated visually and audibly. An additional ring of shortened segments, with their accompanying solid ring and bridging brushes, is provided and the whole ring is capable of slight displacement in either direction. The additional ring is fed with incoming spacing and marking pulses in the same manner as the usual shortened receiving segments, and at each change of sign in the signalling currents relay R_1, also controlled by the line signals, removes a short-circuit on relay R_2. If brush b_2 is on a bias segment when this occurs, relay R_2 momentarily operates the bell B and one or other of the bias indicating lamps. R_2 is of the centre-zero type.

It will be seen that, if a spacing bias exists, changes of sign when a segment is traversed will be from negative to positive, and relay R_2 will therefore be operated to flash spacing-bias lamp SBL. If there is a marking bias changes of sign occur on the segment from positive to negative and R_2 will light lamp MBL.

Fig. 120 merely illustrates the broad principles of the scrutineer and it is obvious that many modifications may be made to the indicating arrangement.

In practice the bias-indicating segments would be set backwards (to the left) to give an alarm before the conditions of either (*b*) or (*d*) had been reached. The scrutineer will also give an alarm if phase-creep sets in.

Regenerative Operation of Cable Networks.—France, the home of the regenerative repeater, is in direct communication with her Asiatic and African Colonies from Paris.

Synchronous Gulstad operation, together with a regenerator, secures higher speeds than would be possible with either alone, and this combination is employed on the German-American cable referred to above.

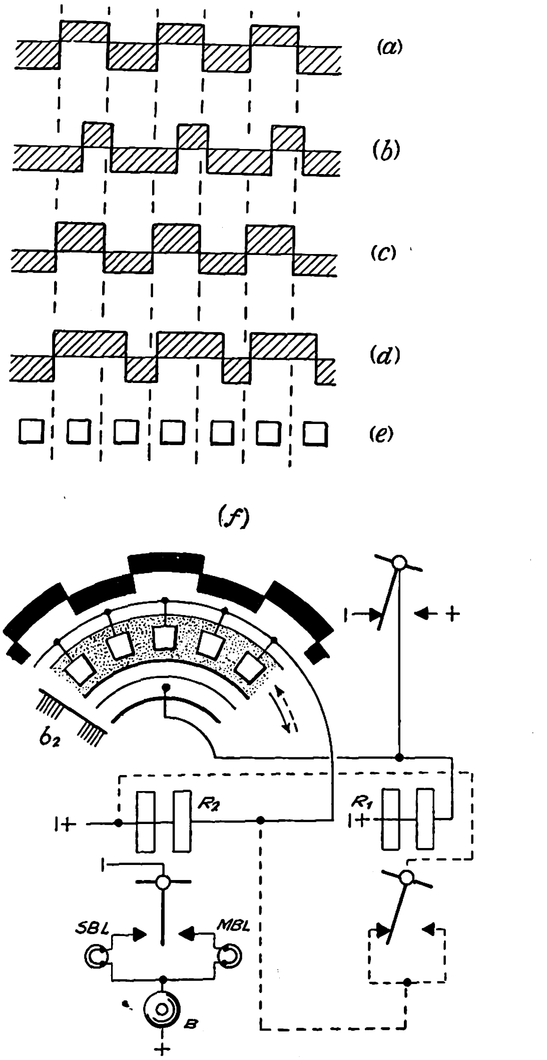

FIG. 120.—Eastern Telegraph Co.'s automatic scrutineer.

The introduction of the regenerator in the case of a large cable network effects considerable economies in staff by reason of the avoidance of retransmission, while it obviates delay and risk of errors in transmission.

Section (6). METHODS OF OPERATION OF LINE PLANT.

Methods of operation of line plant take the form of increased utilization of the line by such means as obtaining several channels by the use of a number of audio frequencies, by superposition, and by dual utilization for telephony and telegraphy.

Composite Working.—Audio-frequency systems have been previously dealt with before this Insitution and there is no need to treat them in this paper. The superimposition of telegraph on telephone circuits is also well understood, and Fig. 121 is given merely to indicate the possibilities of such means.

In June 1918 the American Army equipped a circuit such as that shown in Fig. 121 between Tours and Chaumont, a distance of 306 miles, with a repeater at Autun.

In addition to the three telephone channels the capacity of the 12 both-way telegraph channels was 704 words per minute.

Sub-Audio Telegraphy on Telephone Pairs.—The application of earthed telegraph circuits to telephone pairs in the manner indicated in Fig. 121 is limited. The present-day high-efficiency telephone circuits including loading coils and amplifiers operating with large gains are seriously interfered with by the telegraph currents. This interference is due to the effect of the comparatively large telegraph currents on the permeability of the iron cores of the loading coils, which leads to transient changes in their effective resistance and inductance to telephone currents. The higher harmonics of the telegraph signals are magnified by the amplifiers and furnish another source of interference. These diffi-

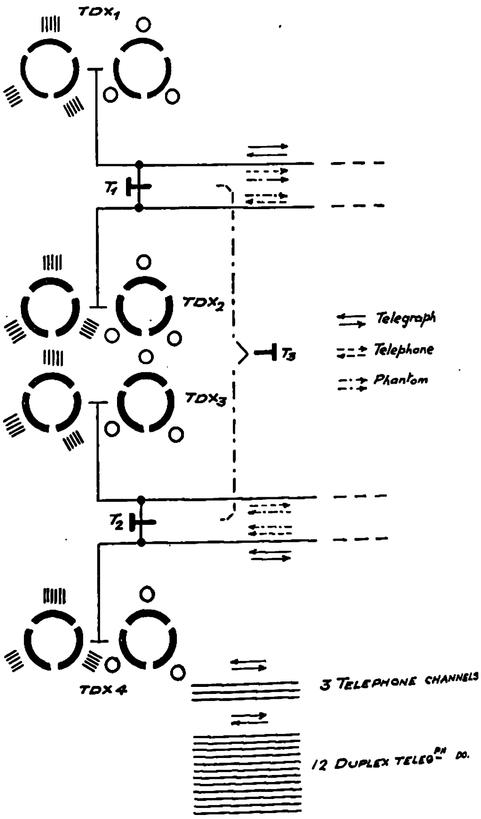

FIG. 121.—Simultaneous telegraphy and telephony on a telephone quad.

culties are overcome by reducing the telegraph currents to a magnitude of the same order as the telephone currents and by employing a complete metallic circuit for the telegraph channel.

Using a metallic circuit for the two channels and operating the telegraph with weak currents, the interference with the telephone by high-frequency components of the telegraph signals is so reduced that it is possible to dispense with much of the " noise-killing " apparatus of the older composite system and greater telegraph speeds are thereby possible. An incidental advantage arises also from the fact that the telegraph currents pass through both windings of the loading coils instead of one coil as in Fig. 121, and the coils thus help telegraph transmission instead of hindering it as previously.

In Fig. 122, L$_1$ and L$_2$ are the two wires forming a coil-loaded telephone pair. At the terminal the line forks, one branch going to the usual telephone apparatus (not shown) and the other to the telegraph apparatus. At the fork, the telephone branch is bridged by series condensers and a shunt inductance—while the telegraph branch is provided with series inductances and a shunt condenser. These are equivalent to high-pass and low-pass filters and when suitably designed effect separation between speech frequencies and the lower band of frequencies forming the components of the telegraph signals. The receiving relay R is double-wound and duplex operation is secured in the usual way by a balancing network BN. The series inductances and shunt capacities in the sending circuit controlled by TL partially suppress the high-frequency components of the telegraph signals. With the arrangement described, the " flutter effect " shown in the inset, which results when the system of Fig. 121 is employed, becomes negligible.

This system is finding considerable application in Germany and it is probable that it will, to a very great extent, supplant the voice-frequency multiple system so widely used in that country.

The system can operate on 2 to 3 mA at 24 volts down to 1 mA at 6 volts, and when applied to cable pairs can be permanently duplexed and will work at a speed of 600 letters per minute (5-unit code) over a distance of 95 miles.

Two-power Multiplex Operation.—The 2-power method of signalling, which has very serious objections when applied in the usual way to morse signalling, can be made much more effective when machine methods of sending are employed.

Fig. 123 (*a*) shows the letters F and L sent by hand on the polarized and non-polarized sides of a diplex or 2-power transmission circuit. Except for any imperfections in the formation of the A-side signals due to manual operation, these will be correctly transmitted and received. The B-side signals are, however, badly distorted. The dash of the letter L is split twice, due to reversals of polarity occurring, and the final dot will probably be clipped at the end. If the two sets of signals are transmitted by two automatic transmitters geared together so that the marking and spacing pulses are of equal duration, as shown in Fig. 123 (*b*), then splits will not occur with B-side dot signals at all, and will only occur at dot intervals during a B-side dash. The tendency to clip the initial or terminal portions of B-side signals has disappeared. It has been found possible in this way to work a 2-power circuit between London and Manchester at 200 words per minute—100 words per minute each side—a hitherto unattainable speed of operation for the B side. The fact that the B-side pulses are always at least of dot signal duration enables the B-side voltage to be reduced as the B-side relay gets more time to act. This fact removes very largely another defect of 2-power duplex operation. Out-of-balance currents are more serious when the B side is in operation, and tend to interfere with the satisfactory operation of the A side. It is possible with the new method to work satisfactorily with a power ratio of 1·5:1

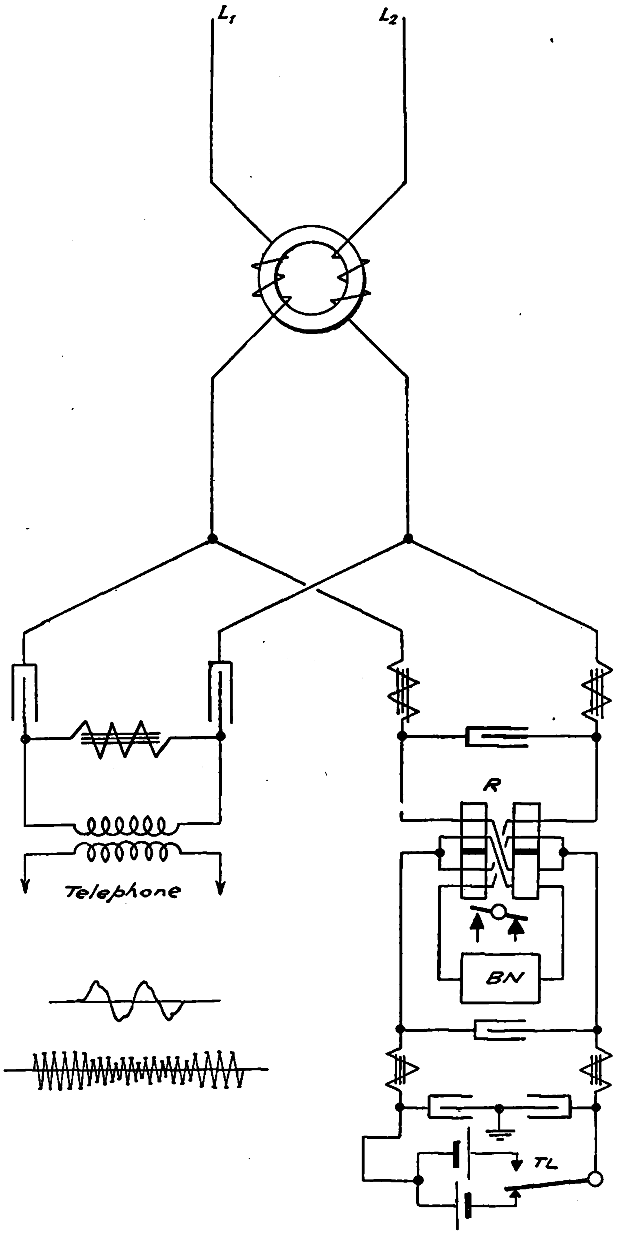

FIG. 122.—Sub-audio telegraphy.

instead of the more usual 3:1, and with a reasonably good balance the operating margin of the circuit is considerably extended.

The idea of timing the two sets of signals so that they originate and terminate together occurred independently and simultaneously to Mr. F. G. Creed and the author* and was applied by Mr. Creed to morse and by the author to 5-unit code operation.

Five-unit code represents the more perfect application of the principle, since the signal pulses of both sets of signals are identical in length and the splitting of signals still present in the improved morse method cannot take place.

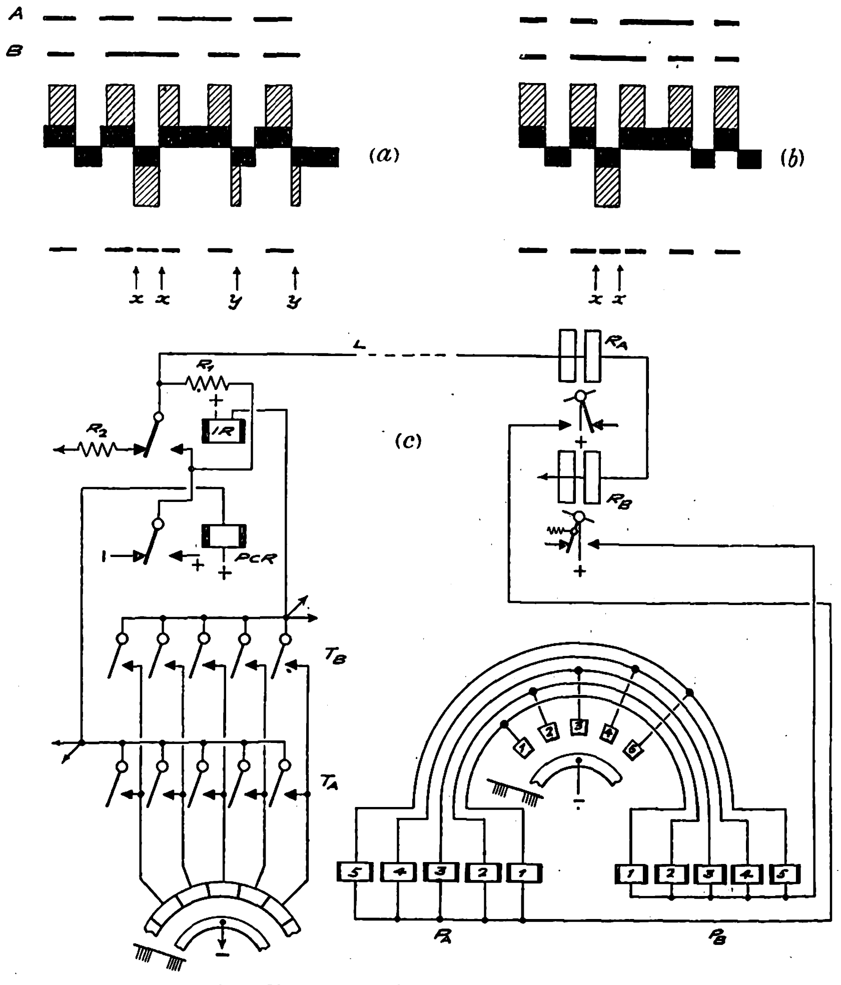

FIG. 123.—Two-power diplex signalling with 5-unit code.

Fig. 123 represents the 5-unit code method applied to diplex operation while quadruplex working is obtained, as will be understood, by employing the duplex balance. Two transmitters, T_A and T_B, are connected in multiple to one channel of a multiplex distributor and are operated independently by perforated tape transmitters, or manually in the usual way by observing a cadence signal. T_A operates a pole-changing relay PCR, and marking and spacing currents are sent out to line in accordance with the combination set up in the transmitter. T_B operates an incrementing relay IR which removes a series resistance R_1 and a shunt resistance R_2 from the line L. This is a well-known 2-power signalling method which needs no description.

At the receiving end the two sets of signals are sorted out by a polarized relay RA responding to the positive and negative currents from the distant A transmitter, while the non-polarized relay RB responds to the incremented positive or negative signals from transmitter B. Such a system, while perhaps not to be recommended for general application, could probably be used to advantage under special circumstances.

Temporary increases of traffic for which no extra line plant is available might be met by the application of this scheme. Also, if the speed of the line is uneconomical for a given required number of channels, the system presents an opportunity of increasing the number of channels to the extent desired.

Temporary communication between a station A and another C forking from a station B could also be obtained.

Morse Multiplex Telegraphy by Division of Line Time.—The application of machine sending to the multiplexing

---

* [British Specifications 221556 and 222616.]

of circuits worked with the morse double-current land-line code provides a solution of this problem free from the defects of the hand-worked Delany multiplex. Here, again, the transmitters must be geared together so that the signal elements originate and terminate simultaneously. Fig. 124 shows the arrangement. T_1 and T_2 are the two transmitters which are geared together and to the brush arm of a sending distributor, so that the uneven-numbered segments are connected to the sending relay R_1 controlled by transmitter T_1, while the even-numbered segments are connected to relay R_2 of transmitter T_2.

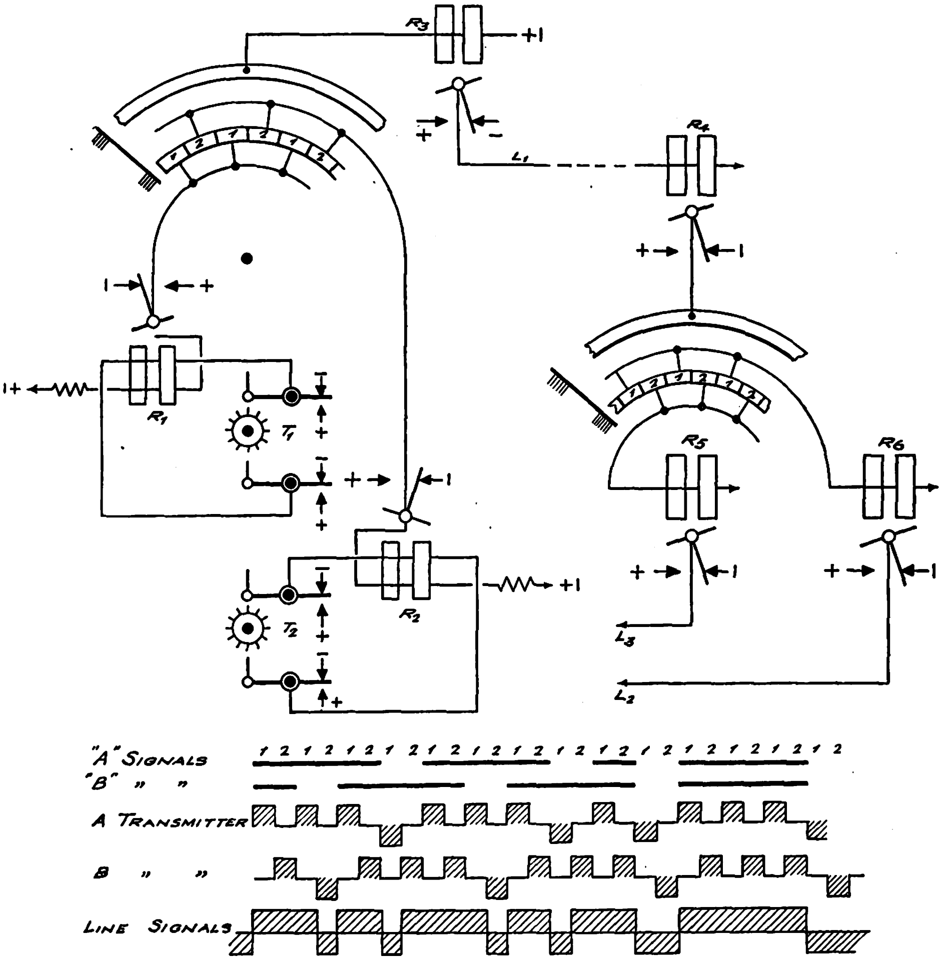

FIG. 124.—Morse multiplex system.

From the current/time chart appended it will be seen that each transmitter is connected through the relays and distributor segments to a third relay R_3, which actually sends the two sets of line signals for a period equal to half only of a signal pulse. T_1 sends during the first half of a signal pulse and T_2 during the second half. The two sets of signals are thus half a signal pulse apart from each other. The combined signals sent out to line are unreadable and the system may be claimed to be partially secret, as the line signals would be difficult to decipher.

At the receiving end the signals are distributed to the two receiving means, which may be two lines L_2 and L_3, or, of course, the signals may be terminated without repetition to distant stations. The receiving distributor is, of course, synchronized, by methods not shown.

Two-channel operation is shown in which the doubled capacity is obtained by halving the length of the signal pulses in the line. For triple or quadruple operation the pulses would be one-third or one-quarter of the signal pulse per channel. The storage feature of polarized relays, neutrally adjusted, is relied on to bring the signal pulses and spaces up to their correct length. Relays R_5 and R_6 may be provided with locking windings to hold the tongues firmly on whatever contact they are set.

With satisfactory synchronism a 2-channel set has worked at 150 words per minute per channel.

Transposition of Land-Line Morse Code.—It has been proposed to operate ocean cables with the Wheatstone-Morse Code at a rate giving a speed in words per minute comparable with the shorter cable code. A method of doing this is to speed up so that Morse Code reversals do not get through, these being interpolated by means of the Gulstad relay or similar device. The disadvantage of this arrangement is that the higher rate of transmission increases the difficulty of obtaining a satisfactory duplex balance. A method has been worked out by the Western Union Cable Co., by which Wheatstone Code may be employed in a cable code transmitter, transmitted to the cable, converted into a code consisting of positive, negative and zero units, and transposed at the receiving end into the original Wheatstone-Morse Code.

The Wheatstone-Morse Code may be resolved into three combinations, each containing two signal impulse units. Thus the letter "1" and its succeeding space is made up as follows:— (+ −) (+ +) (+ −) (+ −) (+ −) (− −).

If it is possible to substitute for the (+ −) type (which is a reversal) a positive pulse of the same time length, for the (+ +) combination a negative pulse and for the (− −) combination a zero unit, the Wheatstone-Morse is then converted into another code of the cable-code type. Further, the individual signal elements are of doubled length and the new code can be transmitted at a rate exactly double that of the original Wheatstone-Morse, while the speed in centre holes is only the same as it would be if the cable code morse were used. In this way it is possible to link, by means of a submarine cable, two land lines working Wheatstone without the sacrifice of overall speed which would be entailed by employing the Wheatstone Code throughout. At the sending end the conversion is attained without any alteration whatever to the standard cable-code transmitter.

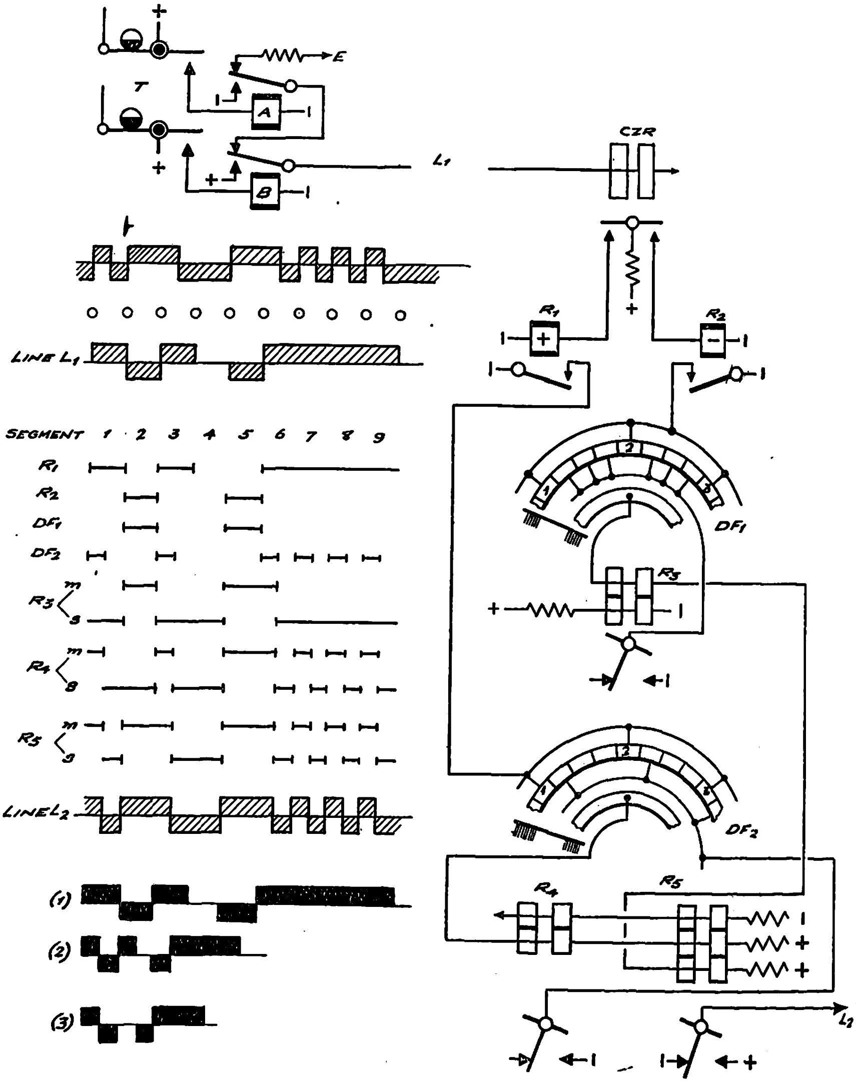

FIG. 125.—Western Union Co.'s transposing system.

Fig. 125 describes the sending- and receiving-end arrangements. The dot pecker enters the upper row of holes, and the dash pecker the lower row. Two relays, A and B, are controlled by the peckers, so that when relay A is operated a negative signal pulse is applied to the cable, while relay B when operated applies a positive pulse with both relays in their normal unoperated position. The cable is earthed when both peckers enter holes in the tape simultaneously (a Wheatstone dot) and both relays operate, but only relay B is effective and a positive signal pulse is transmitted for a time corresponding to the passage of the tape through a distance equal to the pitch of the tape-feed centre holes. When the dot pecker enters the upper hole, initiating a dash signal, a negative pulse of equal length is applied. At the lower hole terminating the dash, relay B applies a positive pulse, and when a space occurs between letters neither pecker operates and an interval of no current occurs of time value equal to that of either positive or negative signal pulses. The Wheatstone letter " A " is thus sent out as (+ +) (− −) (+ +) (0 0).

At the receiving end, the positive, negative and zero units are received on a cable relay CZR of the Brown type in which zero signal intervals have no effect, while positive or negative pulses operate relays R_1 and R_2.

A synchronous distributor is employed having faces DF_1 and DF_2 by means of which the hybrid code is transposed back into standard Wheatstone-Morse.

Relay R_3, operated from DF_1, is in series with one operating winding of R_5, and both are energized by R_2 when a negative pulse is received.

Relay R_4 is operated in series with a second operating winding of R_5 and both are energized by R_1 when a positive pulse is received.

Relays R_3, R_4 and R_5 are normally held in the spacing position by biasing windings in which a current, lower than the operating currents, permanently circulates.

If a negative pulse is received, R_2 operates and completes a circuit via its armature from negative to, say, segment No. 1 and solid ring of DF_1, operating windings of relays R_3 and R_5 to positive. R_3 operates and maintains both itself and R_5 energized over the three segments of DF_1, which follow segment No. 1 until segment No. 2 is reached. R_5 has reversed its armature and is sending out a positive signal pulse to the land line L_2. If, when segment 2 is reached, the same condition prevails, everything is as previously described, and so on.

If a positive pulse is received, R_1 operates and energizes relays R_4 and R_5. R_4 applies negative current via DF_2 and the segment adjacent to, say, segment No. 1, the solid ring of DF_2, its own operated winding and that of R_5. When, however, the next two segments between Nos. 1 and 2 of DF_2 are reached, they are insulated and the biasing windings of R_4 and R_5 operate, the circuit from the armatures of R_1 and R_4 now being broken. R_5 now reverses, and the long positive pulse has thus been transposed into a Wheatstone reversal.

The operation of the entire system is shown by the current/time chart given, in which (1) represents the signals sent into the cable, (2) the signals speeded up to the rate at which dot pulses can be sent through the cable, and (3) the same letters " a," " b," sent in cable code.

It will be seen that the resultant code given by this transposing method is only slightly inferior to the cable code, while the advantage of being able to link the two land lines up via the cable and to employ standard apparatus such as the Wheatstone-Creed more than outweighs the slight loss of speed which results.

Duplex Operation of Long Cables.—Duplex operation of long cables is especially difficult when delicate amplifiers are employed in the receiving branch of the circuit. This arises from imperfections in the duplex balance, which result in outgoing signal pulses entering the receiving branch and not only swamping the weak signals incoming from the distant station but producing false signals in the receiver. The magnitude of this disturbance depends upon the out-of-balance quantity which exists, while it is only transient in character and is at a maximum when a voltage is impressed on the cable at the sending end or a reversal of voltage is effected.

It occurred to the author some years ago that if the receiving apparatus could be cut off from the line during the transient outgoing disturbance, duplex operation could be improved. This involves synchronous distributors and also an adjustment of signalling speeds so that incoming and outgoing pulses are in phase with one another. The arrangement worked out and submitted to the Western Union Co. is shown in Fig. 126. Incoming signal pulses are received alternately on two relays A and B, which are intermittently connected in the receiving branch of the bridge circuit through the shortened segments of the receiving face RF_1 of a distributor.

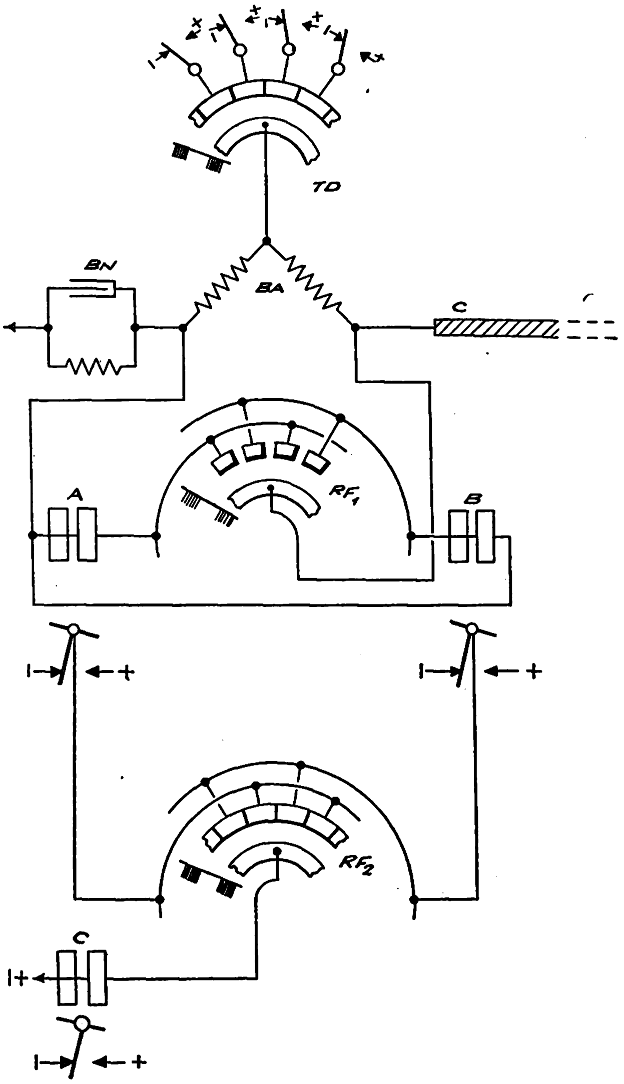

FIG. 126.—Method of eliminating " jar " on duplex circuits.

The receiving circuit is open at the times of greatest disturbance from the transmitter, provided the "in-phase" adjustment, previously mentioned, is secured. The received signals are regenerated by means of the second receiving face RF_2 and relay C. If the line lag is not equal in each direction, speeds must be so adjusted that it is represented by one or more complete segments of the distributors. The same idea subsequently occurred to the Western Electric Co.*

Two-way Working on Loaded Cables.—On long ocean cables of the loaded type the transmission is of the wave propagation character as distinct from the diffusion process in the unloaded cable. In the case of the loaded cable, the received current is zero from $t = 0$ to $t = T$, where $T = L\sqrt{(CL)}$. At this moment the current

$$i = 2E\sqrt{\left(\frac{C}{L}\right)}\epsilon^{-\frac{1}{2}LR\sqrt{(C/L)}}$$

suddenly rises to i and then increases gradually to its steady-state value in accordance with the equation. Such an arrival curve is shown in Fig. 127(*a*).

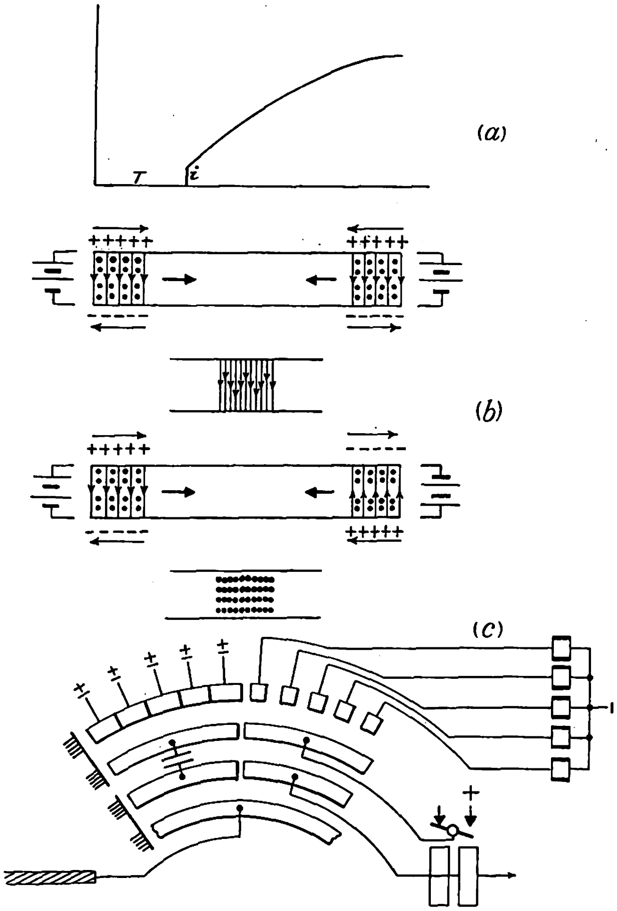

FIG. 127.—Two-way working on loaded conductors.

If wave pulses are sent from both ends simultaneously the electromagnetic pulses meet somewhere in the cable and two cases arise, as shown in Fig. 127(*b*). At coalescence either a doubled electric field or a doubled magnetic field is produced, and this breaks up into two pure waves proceeding to the two terminals of the cable. Thus it is possible to send pulses simultaneously from both ends of the cable and they will pass each other *en route* without interference. Based on these principles the Western Electric Co. have designed a method of 2-way working without the duplex balance in which the usual propagation contacts are not required.

In Fig. 127 the arrangement is shown in which the speed of the distributors is such that the time occupied by the brush arm in passing over one set of 5 segments is equal to the propagation time. The distributors merely switch over from sending to receiving simultaneously and the transmission and reception of one letter requires a time equal to $2T$. T may have varying values and this can be met either by alteration of distributor speeds or by using lengthening networks, or both. It is obviously possible for T to be great enough for more than one 2-way channel to be provided. Figs. 128(*a*) and (*b*) constitute a comparison of two cables, one, (*a*) loaded, the other (*b*) unloaded, in which the times of propagation are assumed equal. In the latter case it will be seen that "propagation contacts" representing a time $2T$ are required to secure both-way operation and the capacity for traffic is reduced by one-half.

Distortion Correction on Long Cables.—The voltage received on a long submarine cable at the ordinary signalling frequency is of the order of 2 to 5 mV. The power available is of the order of 2×10^{-8} watt, and no recorder is known which will operate on such power except at extremely low speeds. Magnifiers of the Cox, Heurtley and electrolytic tape types are well known, but their power output is so small that they can only operate a siphon recorder or an extremely sensitive moving-coil relay. Step-up arrangements may, of course, be employed by which a robust relay is finally operated and a considerable power output obtained. The maximum speed of operation of such devices is about 15 cycles per second.

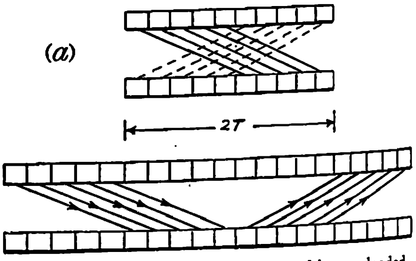

FIG. 128.—Comparison of 2-way working on loaded and unloaded conductors.

The vacuum-tube amplifier contains no delicate parts and maintains its adjustment indefinitely. It has no distorting effects on the signals and it permits distortion-correcting circuits to be readily applied.

The principle on which the vacuum-tube amplifier employed on submarine cables rests is that of producing the various derivatives of the arrival curve, amplifying them and superposing them on the primitive curve. This is already done approximately by the well-known reading condenser which gives a resultant current in the receiver approximately equal to the primitive and its first derivative. The vacuum-tube amplifier allows this process to be carried very much farther.

---

* British Patent No. 228211.

The principal work on this subject has been done by Carson, Mathes, K. W. Wagner and others.

Austin M. Curtis lays down the requirements of such an amplifier to be as follows:—It must take an input signal having components as low as 0·5 mV and as high as 10 volts in amplitude and correct the distortion by amplifying the weaker components much more than the stronger, at the same time making any necessary phase corrections. It must operate satisfactorily with signals having weaker components as strong as 100 mV. An output of about 15 mA at 15 volts should be available, adjustable by small steps. It must be capable of handling currents containing frequencies between a small fraction of a cycle and about 180 cycles, the particular part of this band of frequencies which is to be utilized depending on the cable and the speed at which it is operated.

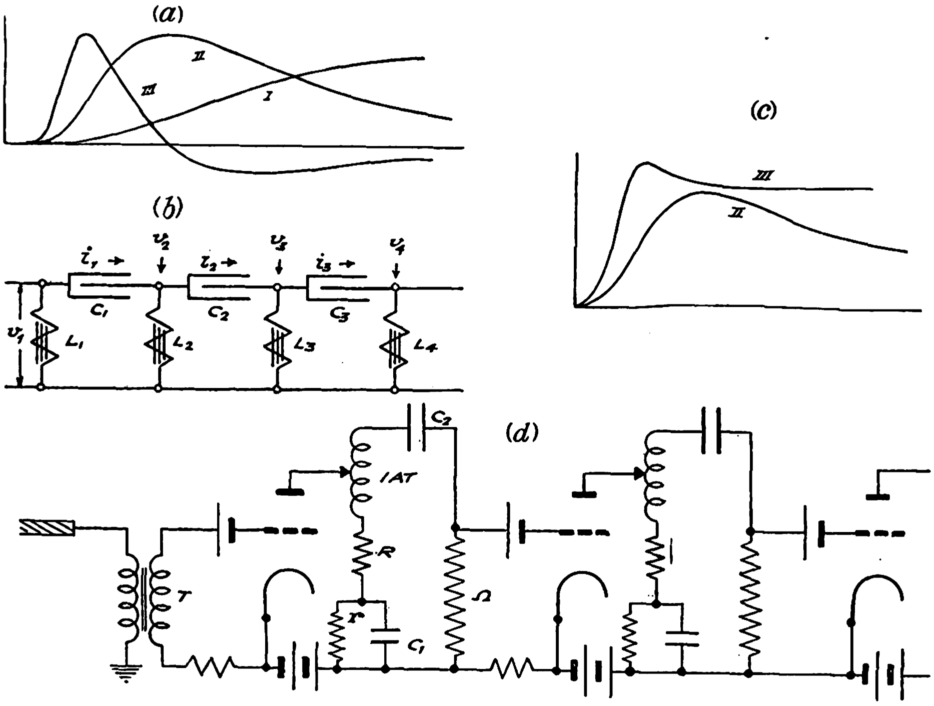

FIG. 129.—Valve amplifier with means for correcting distortion.

The amplification should increase to a maximum at about 1·5 times the signalling frequency, falling to zero at about twice this frequency. This eliminates the higher frequencies and results in suppressing the interfering currents lying above the band of frequencies required to form the signal.

An amplifier designed on these lines permits speeds up to 90 cycles per second, which equals, in cable code, 2 800 letters per minute. It is not entirely suitable for multiplex printing telegraph, as the longer pulses occurring in the 5-unit code necessitate the addition of apparatus to prevent " zero wander."

The conditions to be met in an amplifier of this type will be understood by consideration of the curves in Fig. 129(*a*). Curve 1 represents the arrival current at the receiving end of an ocean cable. Due to its low rate of building-up, rapid signalling is impossible. If a current of this form flows through an inductance, the voltage developed in this will be $L\,.\,di/dt$ as shown in curve II, Fig. 129(*a*), which represents to some scale the time rate of change of the arrival curve. If the current according to curve II is caused to flow through a second inductance, then the voltage across this will be $L\,.\,d^2i/dt^2$ or proportional to the second derivative (III) of the arrival curve. Proceeding in this way the third, fourth and higher derivatives may be obtained.

The amplitude of the derivatives is, of course, much less than that shown, the ordinates having been increased for convenience. It will be seen that successive derivates have a progressively sharper rise which is the required property for a received signal, but on the other hand have no tail, which is disadvantageous, as the signal is not sufficiently sustained. To get both features, viz. sharp rise and sustained amplitude or tail, the network must be arranged to combine all the derivatives in a single circuit.

Successive differentiation can be carried out by a network of shunt and series impedance, and one example is shown in Fig. 129(*b*). The voltage across inductance L_1 is $v_1 = L\,.\,di/dt$, where i is the arriving current. This voltage applied to condenser C_1 produces a current $i_1 = C_1\,.\,dv_1/dt = C_1\,.\,d^2i/dt^2$. The voltage v_2 across L_2 is thus $L\,.\,d^3i/dt^3$ and the current in $C_2 = i_2 = L\,.\,d^4i/dt^4$, and so on. With n meshes, the network will yield the nth derivative. If series resistances " r " are applied to the shunt and shunt resistances R to the series impedances, differentiation proceeds as before but all the derivates are then combined and appear as components in the output wave. Fig. 129 (*d*) shows a combined amplifier and distortion correction network due to Carson. The cable is coupled to the receiving network by a transformer T. The effect of the transformer is to deliver to the amplifier circuit a current approximating the first derivative of the arrival current. This is amplified by the first valve and delivered to the primary of an intermediate auto-transformer IAT. The secondary output from IAT will be proportional to the second derivative, but the resistance R maintains the first derivative. The condenser C_1, having the voltage dv_1/dt impressed on it, passes the current i which is approximately the arrival curve, the condenser exercising an integrating effect. Thus the arrival curve and its first and second derivatives appear at the output of the first-stage amplifier, which is coupled to the second by the large capacity C_2 and high resistance Ω.

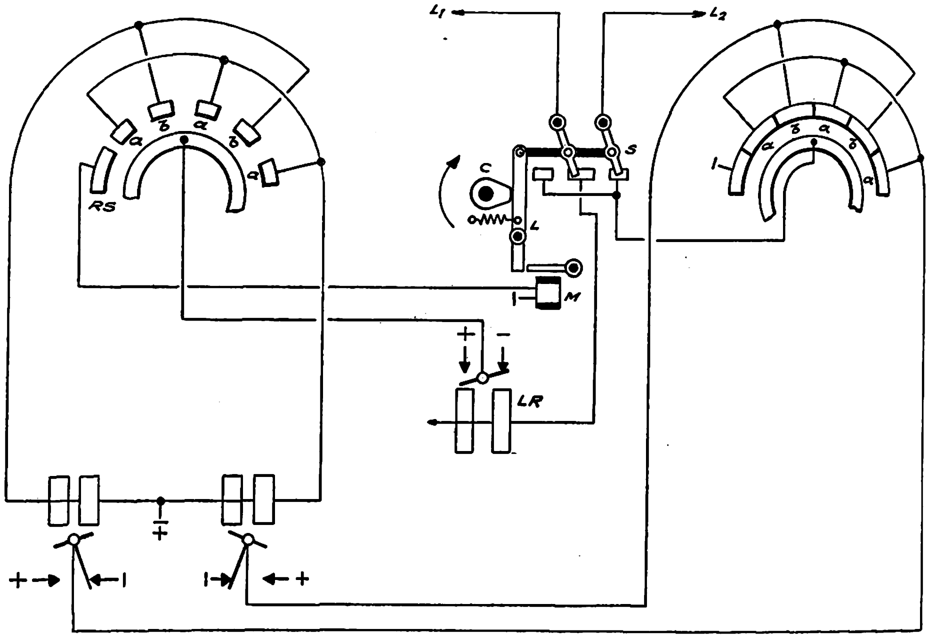

FIG. 130.—Channel reversal method.

Curve II [Fig. 129(*c*)] represents the type of signal obtained with two stages, and curve III that with three stages of amplification and distortion correction.

Channel Reversing.—On a long circuit working through regenerative repeaters in which both-way working does not depend upon the duplex balance, it is sometimes desirable to reverse the direction of operation of one or more channels to accommodate the traffic, which may be heavier in the direction BA than in the direction AB. Usually such both-way circuits are worked two channels AB and two channels BA (in the case of a quadruple), and the reversal of one channel will give a traffic capacity of 1·5:1 as against 1:1. Fig. 130 represents an arrangement which has been employed by the French Administration for a number of years. The diagram is drawn for a repeater station, but either line L_1 or L_2 may be considered as a terminal.

S is a switch which, in the position shown, connects up L_1 to line relay LR, so that signals are repeated, on the sector shown, from L_1 to L_2. The switch is controlled by a lever L controlled by a cam C on the distributor shaft, and a magnet M. If magnet M is operated when the low side of cam C is presented to L, the upper end of L moves to the left under the action of a coiled spring and reverses the position of switch S. Normally this operation is prevented by the fact that, in the de-energized condition of M, its armature abuts against the lower end of L and prevents its movement.

If now station B at the end of L_2 requires an additional channel, the operator at A applies a positive pulse by means of a switch to a special segment preceding the 5 transmitting segments of the sector to be reversed. This pulse is received at the repeater station by line relay LR and a local current sent via segment RS to magnet M, which reverses switch S in the manner previously described. The control of this sector has now passed to B and the normal condition can only again be realized by a special switching pulse from this station.

The necessity for direction control of the type just described is necessitated where long loaded ocean cables furnish several channels on the principle of division of line time.

It is extremely difficult to obtain a working duplex balance at high speeds on such cables, and they are at present operated in one direction for a predetermined period of time and then switched over by automatically operated direction-control apparatus at each terminal station. The direction of operation is governed by switches at each station.

Automatic Direction Control.—Fig. 131 illustrates the principles on which automatic direction control is applied to the 1926 North Atlantic loaded cable. Motor M_1 drives, through gearing, the brush arms over the various faces of the distributors. By means of step-down gears it also rotates at different rates a series of cams C_a, C_b and C_c. After the lapse of a certain time the closure of the contact springs of each cam will coincide, and when this coincidence takes place a circuit is completed for motor M_2 via the springs of C_c and C_b. Motor M_2 tends to drive through a friction clutch FC and second series of cams C_1 to C_4, but these are restrained by electromagnetic escapement E. Shortly afterwards the magnet of E receives a stepping pulse via the three control cams of the first group, and the second group of cams are stepped forward. When the shaft carrying cams C_1 to C_4 is stepped-off normal, the springs of cam C_4 establish a circuit for the magnet of E via the fifth distributor face in the lower part of the diagram. The shaft controlled by the escapement is now intermittently stepped on automatically until the group of cams it controls have made half a revolution. 120 teeth are provided on the escapement wheel and when it has made 60 steps the position of cams C_1 to C_4 is such that their springs are reversed and the system changes over from receiving to transmitting or vice versa. The change-over takes 6 seconds to effect, once the necessary conditions are set up, but the frequency of change-over is determined by the gears and cams controlled by motor M_1 and can of course be set for any desired period. The feature of this arrangement is that the direction control is automatic and starts simultaneously at both terminals.

The correction devices have to be modified, one to step back the brushes on correction and the other to step them forward. The reason for this lies in the fact that one distributor runs slightly faster than the other and is corrected by stepping the brushes back. When the direction of transmission is changed, the receiving station, which is also the corrected station, has now to transmit and the other distributor, which is now the corrected station, runs at a slightly lower speed and therefore must be stepped forward on correction. If this were not done the speeds would have to be adjusted each time a change of direction took place.

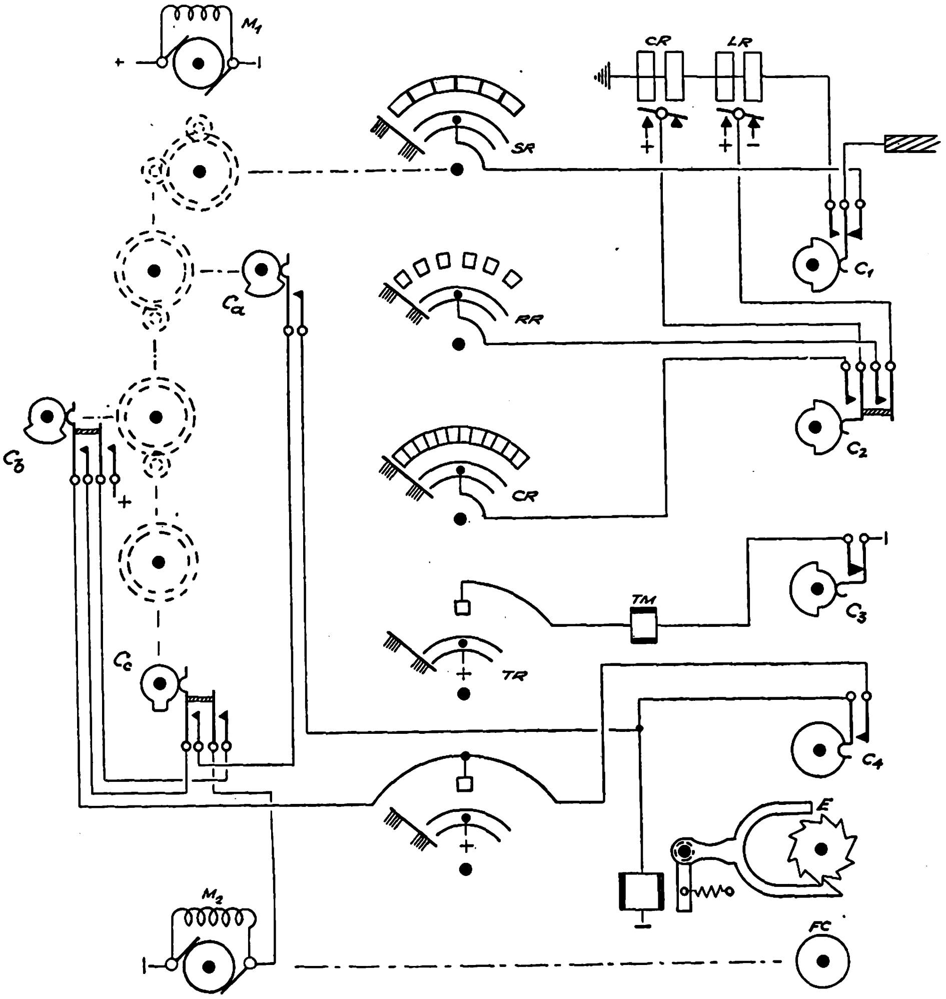

FIG. 131.—Automatic direction control on Atlantic cable.

Section (7). START-STOP MACHINE TELEGRAPH OPERATION.

General.—Start-stop operation of machine telegraphs is invariably of the single-channel type, although this is not a fundamental condition. Its characteristic feature is that all rotary mechanisms, distributors, printers, or a battery of cams determining printer operation, complete one cycle for each letter transmitted.

The synchronism required is relatively coarse and easily attained and maintained. Duplex operation is, of course, possible, and, on circuits where the traffic is not too heavy, transmission and reception can proceed simultaneously with one operator, as reception only amounts to gumming a tape on a message blank. This "one man" system of duplex operation is becoming general. Speeds of 40 to 65 words per minute are possible, and, where line plant between towns is adequate, start-stop channels are more economical than multiplex since they will carry more traffic with less staff. It can be superposed on telephone pairs, interlinked with main-line multiplex systems, and lends itself admirably to any scheme of exchange switching. There is no limitation to the length of line over which it may be operated, and start-stop regenerative repeaters can be applied wherever necessary. For very long links, however, multiplex operation will be retained—the start-stop system finding its sphere of application to inland traffic—while the multiplex will cater for costly international circuits. The early start-stop systems may be described as all-electric, but these are being almost completely superseded by those systems in which the mechanical distributor of Baudot is employed.

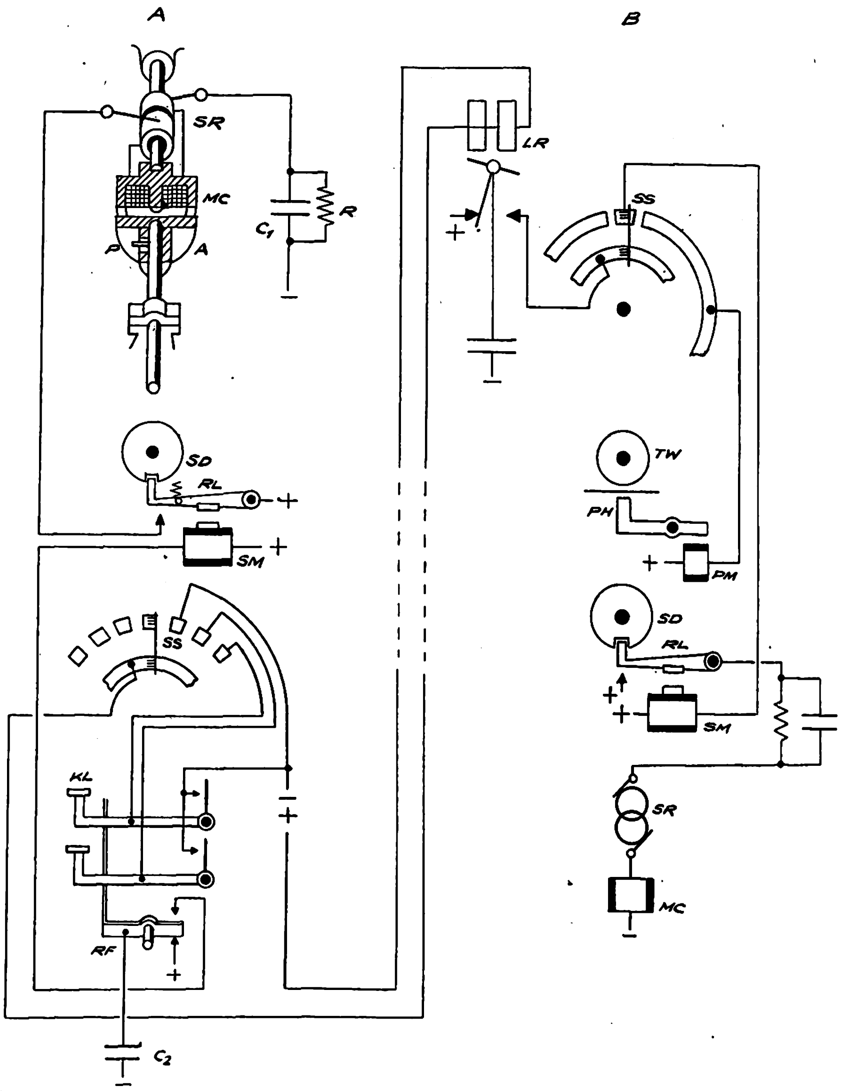

FIG. 132.—Siemens and Halske's start-stop Hughes system.

All-electric Systems.—Two examples of the all-electric type are dealt with. Fig. 132, an arrangement due to Siemens and Halske, may be described as a start-stop Hughes system, in which, however, only one letter is sent per revolution of the apparatus. At station A the sending arrangements are disclosed. A continuously rotating motor (not shown) drives a shaft carrying the exciting coil of a magnetic clutch MC. This portion of the clutch is rigid on the shaft and is fed by slip-rings SR on which brushes rest. In line with the first shaft is a second one which carries an iron armature A rotating with this shaft but capable of sliding along it within certain limits determined by a slot and pin P. The second shaft is normally restrained from rotation by the stop disc SD in a slot of which the pointed end of a release lever RL enters. RL can be withdrawn by a start magnet SM. The second shaft, when released, makes one revolution sweeping over a start segment SS and a number of segments, one for each character. A number of key levers KL are provided, each adapted to apply the negative pole of a battery to its corresponding segment, the positive pole being connected to earth or a second line. When any key lever is operated it rocks a frame RF which completes the circuit for the start magnet SM. The operation is as follows:—

When KL is operated it causes the normally-charged condenser C_2 to discharge via the upper contact of RF through SM. SM operates and frees the secondary shaft and closes a circuit from positive via its armature and lower contact slip-rings SR and clutch magnet winding to negative through a condenser C_1 shunted by a resistance R. C_1 allows of a powerful initial current in the coils of MC, while the resistance R cuts this down to a sufficient strength to exert a good holding effect. The armature A on the second is pulled towards the other half of the magnetic clutch and the two shafts are coupled together. This condition is maintained for a whole revolution as the release lever RL is held on its circuit by the stop disc SD. At the end of the revolution, RL snaps up into the slot in SD, disconnecting the clutch circuit and positively stopping the second shaft.

When the distributor brush-arm moves from normal it first sends out a start pulse from negative, start segment SS, solid ring line L_2, line relay LR at station B, line L_1 to positive. As it continues rotating, the brush arm encounters the segment corresponding to the operated key lever KL and another pulse is sent over the line. Each letter thus consists of a start pulse and a letter-signal pulse, and the various letters are differentiated from one another by the interval between start and signal pulses.

At the receiving end, station B, the start pulse moves line relay on to its operating contact and a normally-charged condenser is discharged via the relay tongue segment SS of the distributor through the windings of start magnet SM. The distributor shaft carries a type wheel TW against which a paper tape is forced by a printing hammer PH operated by a printing magnet PM. Since both distributors are in phase and as the type on the type face of TW occupies the same positions assigned to the letter-signal segments, it follows that the letter printed will correspond to the key lever operated at station A.

This system operates extremely well and at speeds higher than either the Hughes or the ordinary stock ticker. Its disadvantage is that it cannot be interlinked with a circuit using 5-unit code, unless costly transposing arrangements are provided.

Tape Control of Transmission.—Tape transmission is applicable to start-stop operation and is specially advantageous in the case of news distribution from a central news agency to a number of subscribers. In this case it is usual to run the sending distributor constantly while arranging for it to send out a start pulse once per revolution to maintain the necessary degree of synchronism at the receiving station or stations.

Fig. 133 shows an arrangement of this character employed by the Morkrum Co.—now the Teletype Corporation—of America. T is a tape-controlled transmitter of the type in which the tape is stepped forward by a pawl-and-ratchet mechanism letter by letter by a stepping magnet TM. The stepping of the transmitter is accomplished by a cam TC which, at the right moment and once per revolution, closes the circuit from an earthed battery to the magnet TM. This circuit passes differentially through the two windings of a relay SR via its armature back contact and via a contact of a tape control rod TCR. Relay SR does not operate under these conditions and TM is regularly stepped on once per revolution. The tape is fed directly from a per-

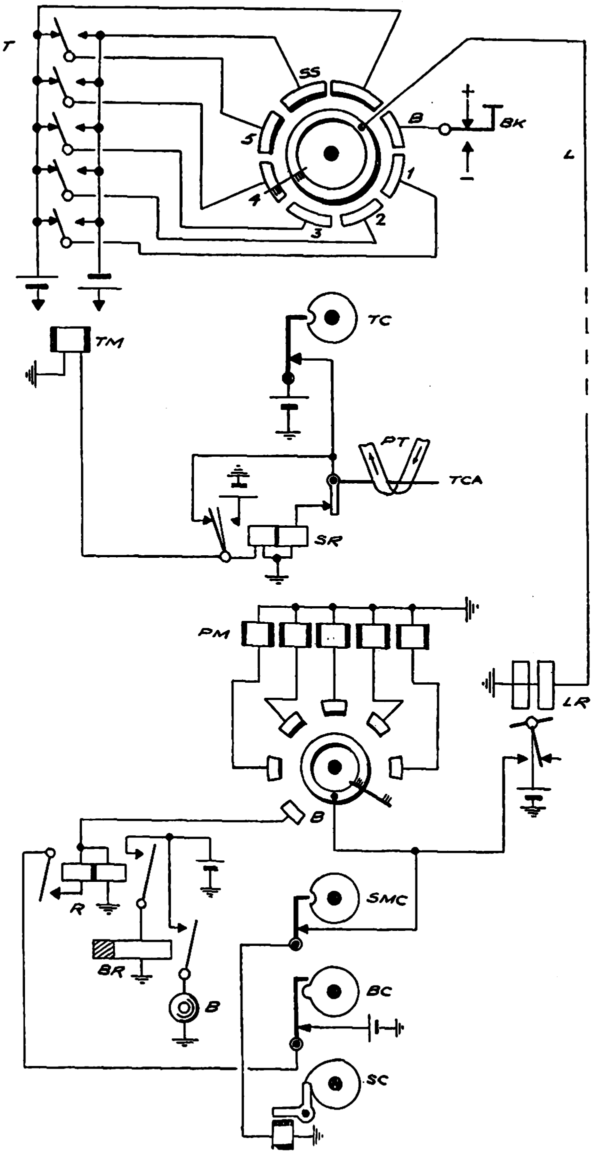

FIG. 133.—Automatic start-stop system for 5-unit code.

forator to the transmitter and forms a loop of varying length. If perforation stops or if the rate of perforation is lower than that of transmission, the tape loop shortens and ultimately lifts the long arm of TCR, breaking the circuit of one winding of relay SR. On the next stepping pulse from TC, only one winding of SR is effective and SR operates, locking itself up and permanently energizing TM. TM withdraws the transmitter peckers from the tape and prepares the feeding action for the next letter, but since feeding takes place when TM is de-energized it does not occur. The transmitter levers all go to spacing and no letter signals are sent out.

When the loop of tape lengthens again, TCR falls, connects up the opposing winding of SR and on the next stepping pulse this relay is released and the transmitter functions regularly. This automatic control of a tape-operated transmitter so that it stops when the tape is not supplied regularly and stops between the last letter sent and the next about to be sent, is due to Mr. Donald Murray.

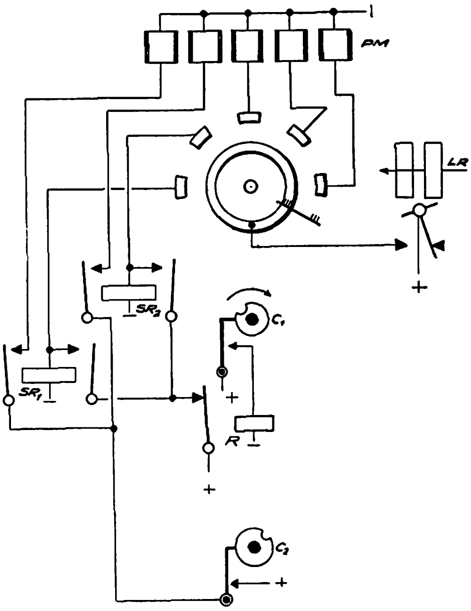

FIG. 134.—Receiving overlap arrangement for start-stop system.

Automatic Transmitter Control.—The stop-start control of the receiving distributor by the continuously-running sending distributor is effected as follows:—As the brush arm revolves at the sending station it sends out to line a negative pulse from start segment SS. This operates the distant line relay LR, and a local circuit is closed via the start magnet cam SMC and its springs to the start magnet SM. SM energizes and releases a shaft driven by a yielding clutch (not shown), and the distributor brushes make one revolution. At the sending end the negative starting pulse is succeeded by a positive spacing pulse, and positive pulse from segment B (the function of which is explained later), and then the 5 transmitting segments which will have positive (spacing) or negative (marking) battery applied to them in accordance with the setting of the transmitter levers of T. These letter signals are received at the distant end and distributed to the 5 printer magnets PM from the line relay via the receiving distributor.

Bell Signalling.—Arrangements are provided by which a code of bell signals can be sent out without interfering with the passage of traffic. This is the object of the segments marked B on each distributor. When the bell key BK is operated at the sending end, it applies negative battery to segment B and this operates signal relay R at the receiving station. R locks up from an earthed battery via the springs of bell cam BC. R operates in turn a slow-to-release relay BR which closes a local circuit for the single-stroke bell B.

When the brush arm comes round again, and before it reaches segment B, the locking circuit of R is broken at cam BC. BR holds up, and, if the distant bell key is still operated, relay R is again energized and maintains BR in the operated condition. Thus only one stroke of the bell is effected for one depression of the distant bell key, regardless of the length of time the key is operated, and there is no need for timing either the moment of operation of BK or the length of its operation.

Overlap at Receiving End.—There are two functions in the start-stop cycle where as much time as possible is required without gaining this at the expense of line time. One of these is at the printer and involves the printing and paper-feeding operations; the other is at the transmitter and refers to the tape-stepping action of the transmitter magnet and the settlement of the transmitter levers against their contacts after the subsidence of all "bounce."

In both cases the necessary time can be obtained by allowing the latter portion of one cycle corresponding to one letter partially to overlap the first portion of the succeeding cycle. Fig. 134 shows such an arrangement for securing overlap at the printer. The first two signal elements of a letter signal are set up on two storage relays SR_1 and SR_2 via the first two contacts of the distributor. They are both locked up through their right-hand contacts from the back contact of relay R, but the signals stored in them are not immediately transferred to the first and second printing magnets. This transfer is accomplished when the third signal element is received, when cam C_2 closes a circuit from positive through the left-hand contacts of SR_1 and SR_2 through the windings of the first and second printer magnets to negative. The remaining three printer magnets are set directly in the usual way. Shortly afterwards the transfer relay R is operated by cam C_1 and opens the locking circuit for relays SR_1 and SR_2, which return to normal. The time represented by two signal elements is thus added to the ordinary printing time by the use of an overlap period.

Overlap at Transmitting End.—The same principle applied to the transmitter is shown in Fig. 135. The distributor here is continuously rotated and sends out start pulses, one per revolution, to control the distant receiving distributor. The first two transmitter levers are directly connected to the distributor, but the third, fourth and fifth of these levers operate three storing relays SR_1 to SR_3. These lock up through their left-hand contacts in an obvious way, while their right-hand contacts repeat the setting of the last three transmitter levers to the distributor.

When this storage has been effected and the signal elements of the first two transmitter levers have been sent to line, the transmitter magnet TM can be operated by cam TC to feed the tape forward. Transmitter levers 3, 4 and 5 must be rendered inoperative at this stage so that they do not interfere in any way with the previous setting of the storage relays, and they are therefore disconnected by cam DC while the three last signal elements of the previous letter are being transmitted. When a letter signal has been completely transmitted, reset cam RC opens the locking circuit for the three storage relays, which release and are immediately ready to be reset. By this overlap arrangement all transmitter levers are at rest firmly on their contacts before the transmission of a letter signal commences.

main office or be extended to start-stop local circuits. Two relay groups are provided, one (RRG) for receiving signals from the main line destined for the local office, and one sending group (SRG) which receives signals from the local office for transmission over the main line to the distant station.

In addition to these, the equipment at the head office embraces a sending start-stop distributor SSD and a receiving start-stop distributor SRD.

Control is effected as follows:—Once per revolution the local ring of the receiving distributor closes a circuit from positive through start magnet SM_1 of SSD, which is thus kept continuously revolving, and sends out a start pulse to start relay SR controlling over line L_2 the receiving start-stop distributor at the branch office. The latter starts up and in doing so also starts up the sending distributor there, which sends a start pulse over line L_1 (a disconnection), and the release of relay RR closes a circuit for start magnet SM_2 and distributor SRD is started up. Thus the start-stop circuit is kept at correct speed and phase with respect to the main-line distributor.

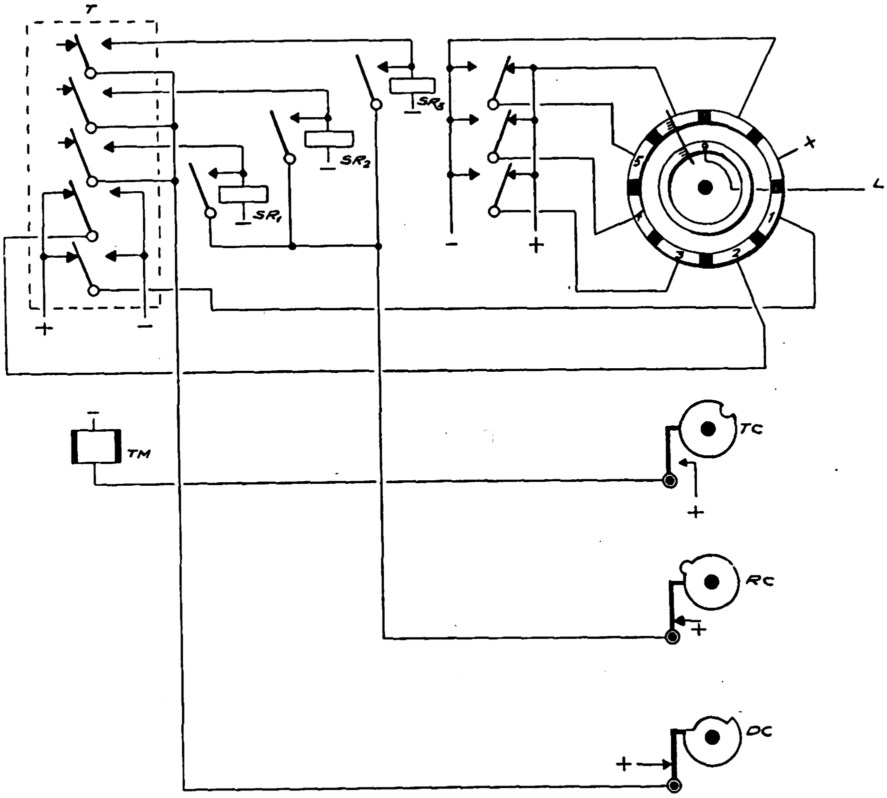

FIG. 135.—Transmitting overlap arrangement for start-stop system.

Interlinking of Start-Stop System with Duplex-Multiplex Circuits.—In Fig. 136 the arrangements at a main office are shown by which a local start-stop circuit may be interlinked over one duplex channel on a multiplex system connected to a main line. The local office is connected to the main office by two lines, one for transmitting and the other for receiving, although, of course, one line could be used by adopting the duplex balance. The local lines are worked on the closed-circuit principle.

The control exercised by the main office on the apparatus at the local office will be more readily understood by assuming that there is no traffic passing from main to local. The equipment at the main office consists of a distributor having a receiving face RDF and a sending face SDF. There are two local rings for control purposes, while other channels (not shown) may terminate at the

The distant transmitter at the branch office is preferably of the tape-controlled type, as, if a keyboard transmitter is employed, this must be normally locked and only unlocked at appropriate times. This, although not an impossible arrangement, is not desirable.

Signals from the branch office pass via SRD to the 5 storage relays SRG, but this does not occur until the main-line sector has been passed over, and the combination set up is not transmitted until the next revolution. Signals from the main line to the branch office are stored in RRG and are retransmitted immediately the sector on RDF has been traversed by the brush arm, and the relay group RRG is reset to normal by cam C after retransmission is completed.

The reciprocal or " flip-flap " control of the stop-start distributor can be dispensed with by increasing the number of relay storage groups, but the most convenient way is to use perforated strip recorders at the main-line station, a perforated tape representing the cheapest form of storage when several letter signals are to be stored.

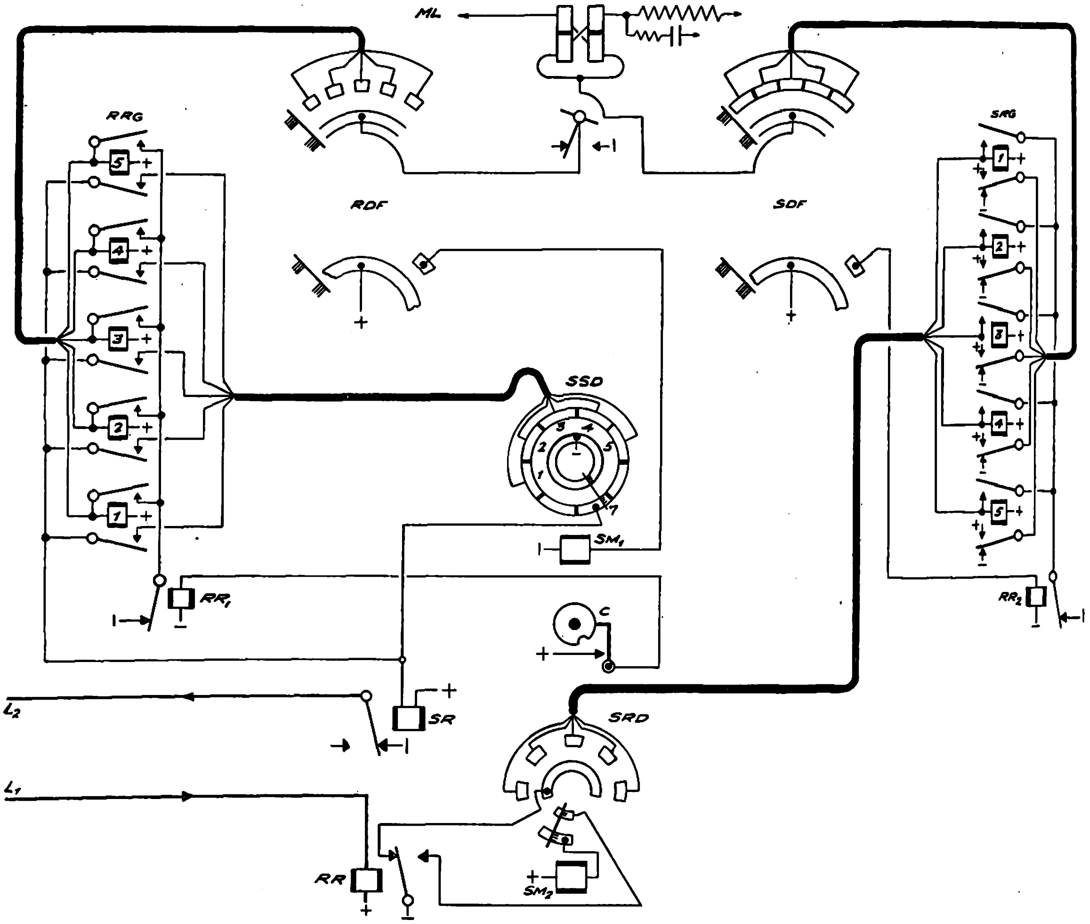

FIG. 136.—Interlinking of start-stop system with high-speed duplex-multiplex system.

Mechanical Distributors.—A comparison of start-stop systems using mechanical distributors involving a single transmitting lever at the sending end and a single magnet in the printer at the receiving end is possible by reference to Fig. 137. The reduction in the number of contacts, circuits, magnets and relays is all in the direction of simplification of maintenance, while the printer operations are all carried out by power drive, electricity only acting as a trigger.

Both the transmitter and receiver have certain common features. In the transmitter the movement of one of a number of levers (the character key lever of the letter to be transmitted) is translated into the current permutations of the letter to be printed at the receiving end. The key lever KL sets a number of combination bars so that they interfere or do not interfere with the movement of a number of levers adapted to oscillate in succession under the control of spiral springs. These levers are arranged to operate in succession on a common bar which oscillates a transmitter lever. Such mechanisms have already been described in Section (2). The start impulse is generated by a sixth lever, which operates invariably when the cam shaft starts into operation, no combination bar being provided to interfere with this. The key lever operates a clutch (not shown) to start the cam shaft and allow it to make one revolution.

At the receiving end the inverse function has to be performed. The same cam-controlled levers are either interfered with or not by a common bar which, in this case, is remotely controlled and therefore operated by a single magnet M. The sixth or start lever does not depend upon the joint action of a cam and the common bar but is released by the action of the bar only, the armature of magnet M. When it operates upon receipt of the start pulse, it trips a mechanism (not shown) which clutches the cam shaft to a power drive for one revolution. Under the interfering action of the common bar A, combination bars are arranged exactly as those of the distant keyboard, a row of slots alined, and one only of a number of selector bars drops into the slots and determines the printing. Bar SB could, of course, control the key lever of a typewriter by intermediate power mechanism, as described in Section (3).

Start-stop mechanism of the type described will represent the type printer of the future until such time as it is replaced, perhaps, by the transmission of a telegram as a picture—not an impossibility.

Section (8). The Future of Machine Telegraphy.

Telegraphy and telephony are nowadays comparable in so far as it may be said of both that they can bridge the distances between any two points on the earth's surface. What the valve amplifier combined with loaded conductors has done for telephony, the regenerative repeater, loaded conductors and the valve have also accomplished for telegraphy.

International telegraphy is remunerative; inland telegraphy, at least in Europe, is in a bad way financially. Inland telegraphy in America is successfully conducted by two privately-owned companies, while telegraphy in Europe is controlled by Government Administrations. The difference in the nature of the control does not, however, account for the degree of success achieved in the one case and the invariable failure in the other. America is a land of long distances, and between two centres with a community of interest the journey by train can easily occupy at least 24 hours. This geographical feature is, naturally, a stimulant to the use of the telegraph, and question, answer, or instruction can readily be handled by telegram where a telephone call would be a needless extravagance.

Long distances operate in favour of the telegraph and against the telephone, and the length and importance of the communication determines which form shall be used. The net effect is that while telephony in America is in a flourishing condition, economic factors enable the telegraph not only to survive but to attain a healthy, strong position alongside its rival.

International telegraphy will always be prosperous because it has a natural aid in the fact that as we move eastward or westward there is a difference of time of 1 hour for each 15 degrees of longitude—a difference which has to be *added* for eastward and *subtracted* for westward progression. This difference of time has no influence on telegraphy but operates against world-wide telephony, due to the fact that in the latter case the overlap of the working day becomes shorter and shorter eastward or westward of Greenwich.

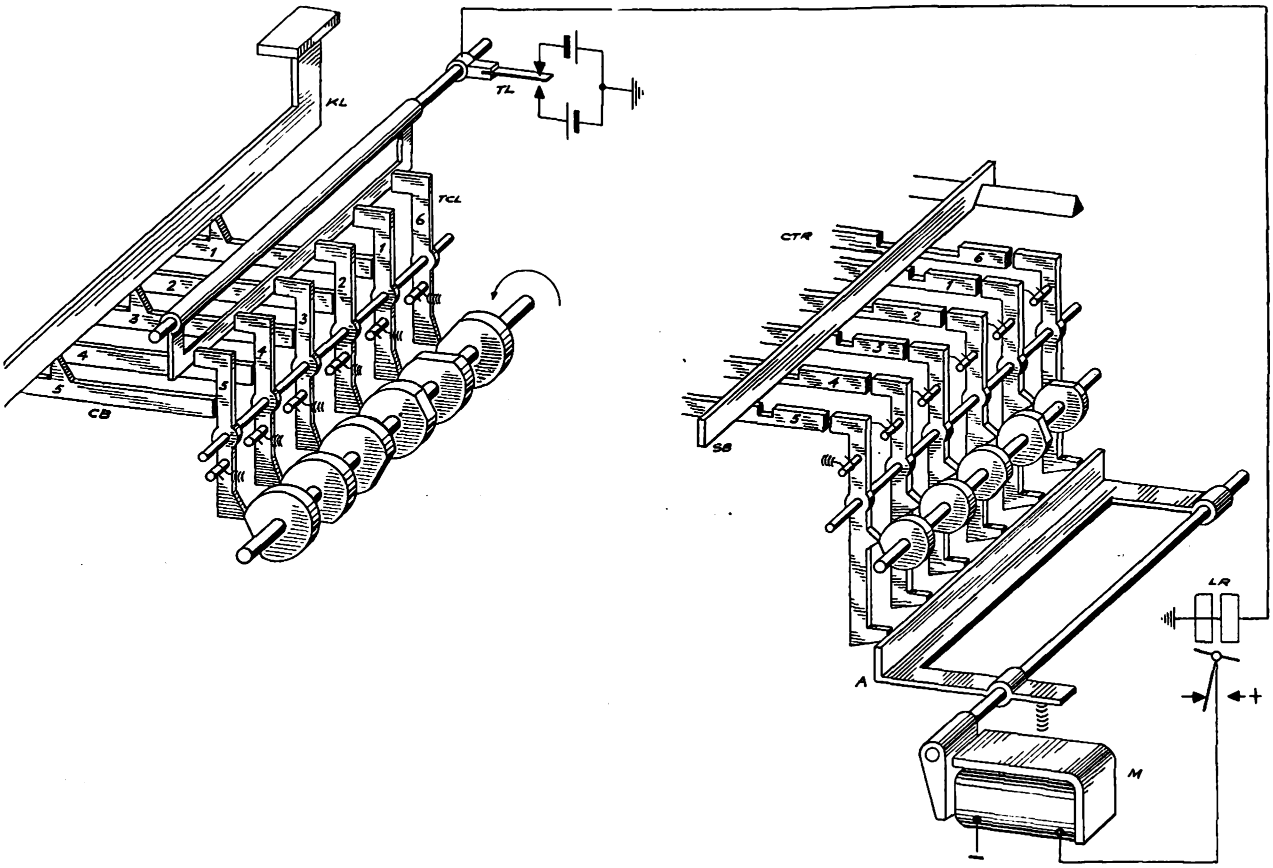

Fig. 137.—Transmitting and receiving arrangements of start-stop system with mechanical distributors.

Neglecting variations due to Summer Time Regulations, the time chart of Fig. 138 is drawn for a total difference of 5 hours westward and 12 hours eastward. The vertical divisions are spaced 15 degrees apart, representing 1 hour of time. The horizontal lines, a distance apart of 1 hour, divide the ordinates into 24 hours or 1 day. The sloping chain-dotted lines are spaced apart by an amount representing 8 hours and cut the Greenwich longitude at 9.0 a.m. and 5.0 p.m., considered to represent that part of the working day at which telegraphing would be effected and telephony normally carried out.

It will be seen that it is possible to telephone westwards (assuming normal business hours) only between 2 and 5 p.m. Talking eastwards must proceed in the morning and, commencing at 9.0 a.m., cannot be carried out further east than China. These differences of time constitute the only factor operating against world-wide telephony. Their sole effect on telegraphy is to cause a change in the direction of traffic, which flows eastward and westward alternately except for short periods where the working day overlaps. So far as Europe is concerned, difference of time has little influence on either inland or international telegraphy.

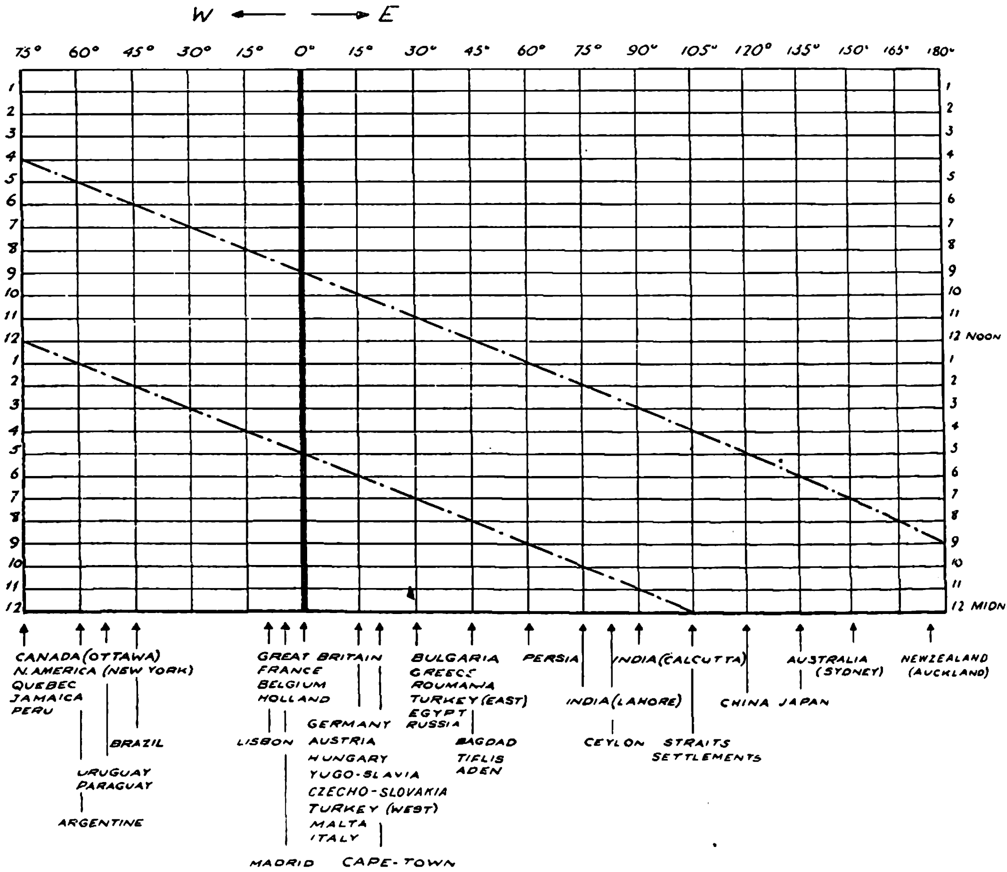

FIG. 138.—Chart indicating time simultaneously prevailing at different world centres.

From the foregoing it is clear that telegraphy (either radio or wired) will survive, and the only problem which has to be solved is the very serious one of making inland telegraphs pay in countries where distances are comparatively short. It has been clearly established in this country that of all the factors contributing to the cost of a telegram—supervision, line plant, office provision and apparatus, engineering and operating cost—the last-named is higher than all the rest put together and that the telegraphs cannot be made to pay until this cost is very considerably lowered.

The fact that joint use may be made of the telephone network for both telegraphy and telephony by methods set out in Section (5) of this paper, and that in this way many more telegraph channels are available than would be needed to carry a much greater traffic than is at present available, suggests one change which might be made.

Securing several channels on one line by the principle of division of line time is costly from a staff point of view. The synchronism which has to be observed requires the careful adjustment of apparatus and constant supervision to secure stable working.

It is only in the case of long, costly links of the transoceanic or transcontinental types that the multiplex method of operation will be justified.

The new factors which have arisen to make the utility of the multiplex for inland working of doubtful value are (1) the perfection of the single-channel start-stop machine telegraph, and (2) the co-ordination of line plant. But even if all the inland multiplex apparatus were scrapped to-morrow and equivalent channels obtained by single-channel start-stop apparatus, the problem of making the telegraphs pay would still persist. The principal factor in the operating cost is the retransmission necessitated by the fact that the originating office and the destined office between which a telegram has to pass are, in a great number of cases, not in direct communication with each other, and the message may have to pass from A to B, B to C and C to D instead of A to D directly. If we allow only 1 minute for such a message, there are 6 operators involved, 3 transmitting and 3 receiving, and 0·1 man-hour is absorbed, whereas if the transmission were direct between A and D the figure would be one-third of this. In this rough calculation no allowance has been made for the time required to collect and distribute the message at the intermediate offices B and C.

The problem to be solved is the abolition of retransmission. There is only one way—it may be called the last phase of machine telegraphy—in which this can be accomplished, and that is by the adoption of machine switching. A theoretical "trunking scheme" for an inland machine telegraph system, in which intercommunication is effected by switching processes well tried out in automatic telephony, is set out in Fig. 139. A main switching centre is shown at M, which would be located at or near to the centre of the network. Lines extend from M to 4 sub-switching centres in the centres of the northern, eastern, western and southern areas, and lines would radiate from these to other smaller centres which would either represent terminal offices or would be subordinate switching centres to the regional sub-centres. A free, through route from an office in any region to one in the same or any other region could be set up by dialling in the manner standard to automatic telephone systems, and the route set up could be held during signalling, without premature release of the switches, by means which have been worked out, while the release condition could be effected by known methods.

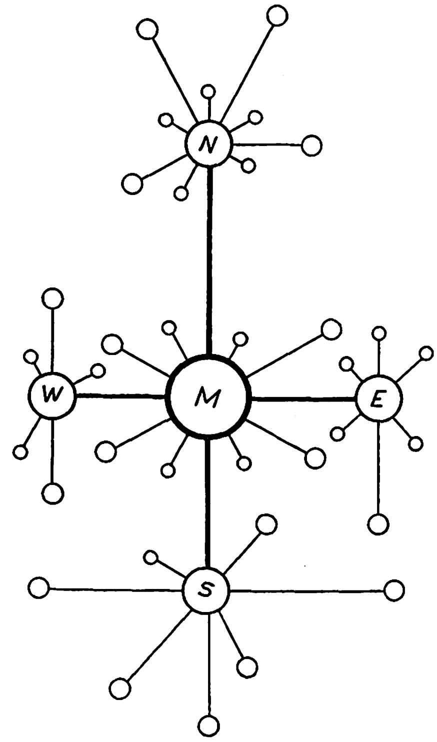

FIG. 139.—Theoretical telegraph network arranged for automatic through-switching.

Where the number of outlets from a switching centre is insufficient to accommodate a rush of traffic at any time, the messages may be stored on perforator-transmitters and stepped off in turn as outlets become available.

The system becomes feasible by reason of the number of telegraph channels rendered available through the combined use of the telephone line plant for both telephony and telegraphy. Such a system can be developed only by the co-operation of the administration, as data are necessary in order to determine the numbering scheme which will route the traffic in the best way. Moreover, such a scheme would certainly have to be applied gradually over a number of years, but yet must be designed from the start to be satisfactory when completed. The telegraph apparatus should be exclusively of the start-stop type.

Such a system as outlined would seem to have the following advantages:—

Considerable saving of operating, collecting and distributing staff.

Speeding-up of the telegraph service by saving the delay arising at retransmitting points.

Making the teletype exchange idea feasible.

The saving of operating staff is a net gain, as they would be replaced by a maintenance staff at the switching centres. The speeding-up of the service would certainly have a stimulating influence on telegraph users, and the larger revenue, with the assumed lower operating costs, would perhaps make it possible to reduce charges.

The regenerative repeater is one example of the reduction of operating costs by substitution of automatic processes for manual, it being well known that the cable companies have been able to make substantial reductions in the staffing at their foreign stations, and in many of these the present staff is a maintenance staff only.

With such a system of automatic through-switching provided on a nation-wide basis it might become practicable, if thought desirable, to institute a zone system of tariffs for telegraph traffic.

Fixed time rates for through-connections of $\frac{1}{2}$ to 1 hour's duration might become possible, the users at the two ends of the connection having their own teletype apparatus and thus relieving the administration of all operating work. Certain exchanges, such as those of the coal, cotton and metal trades could at fixed times in the day simultaneously advise their subscribers of market changes. They would all be provided with teletypes leased or bought outright from the administration, and the extra demand for these would enable the manufacturers to work on the basis of thousands, instead of hundreds as at present.

It is perhaps too much to prophesy the dawn of a Golden Age for telegraphy, but by the adoption of methods outlined above the amount of operative work by the administration would be reduced, firstly by the abolition of retransmission and secondly by the throwing of some operative work on the user himself. If this occurred the telegraph would more closely approach the conditions under which the telephone operates to-day. There are difficulties in the way, but it is the function and the privilege of the engineer to surmount these.

DISCUSSION BEFORE THE INSTITUTION, 27TH MARCH, 1930.

Mr. T. E. Herbert: It is noteworthy that the period of adversity through which telegraphs have been passing has coincided with an amount of progress unparalleled during any corresponding period of the history of the art. Precision methods of speed and phase control are essential on transoceanic cables, but I think that these methods would result in greater stability of working if applied to inland circuits. From this point of view, I consider that the future line of progress will be in the direction of gang control of all multiplex circuits. In general, it is noteworthy that many of the methods described involve interference with the normal rate of vibration of the reed. This plan was given an extensive trial by the Post Office on inland Baudot circuits, but it was found to be less stable than the epicyclic-gear correction. There was some evidence of "jar" when the corrected magnet was energized. I therefore suggest that the correct method of attacking the problem is to decide precisely what amount of deviation from absolute accuracy is permissible without adverse interference with the signals. Having decided upon this value, the correction applied should be purely mechanical—and should not interfere with the normal vibration rate of the resonant system. The Mendonca governor, as described in the paper, is in use by the Post Office and is giving fairly satisfactory results. It has the advantage that the speed control may be varied at the table, whereas in the case of ordinary reed-driven distributors the adjustment has to be made some distance away, as the reed is usually fixed on the wall of the building in order to avoid vibration. On the other hand there is some indication that any variation (due to minor causes) in the load on the driven side of the Mendonca governor produces a definite alteration in speed. The suggestion of inter-office control of all multiplex circuits is particularly attractive, and I think that anything which tends in the direction of greater stability is very valuable, since the crux of the economic problem of telegraphs lies solely in economy of human effort. Considerable capital expenditure is, therefore, amply justified where labour savings can be effected. It should be realized that if the whole of the plant costs were eliminated the problem of the telegraphs would still remain. So far as I am aware, the first example of correction from the signals received is represented by the Hughes apparatus, and the devices employed by Creed are applications of the same basic principle. The various methods of obtaining phase correction of a distributor from the signals themselves are a natural development likely to be universally adopted. Gang driving of all start-stop machines in a large office has many advantages. By the use of synchronous motors all speed adjustments would be rendered unnecessary, and it would be possible to devise some form of concentrator for less busy circuits, thus reducing the total amount of apparatus which it would be necessary to provide. If the public supply of alternating current were accurate enough in periodicity to drive clocks through the medium of a synchronous motor, this problem would clearly be solved in the simplest and most economical manner. The second section of the paper, dealing with transmitters, is particularly interesting in that it brings out the fact that the basic principle of Kleinschmidt, Morkrum and Creed keyboard transmitters was definitely anticipated by Baudot. The elimination of chattering on transmitting contacts is a valuable modern improvement, and in this connection it may be stated that the latest form of Post Office standard relay with cores annealed in an inert gas, and with spring contacts, constitutes a definite improvement on the older form. The suggestion made by the author, that the typewriter form of keyboard should be modified, greatly appeals to me. The original motor-car bodies were designed on the lines of the horse-drawn carriage, and it is only necessary to compare the four-wheeler with a modern motor-car in order to realize how greatly the difference in the method of propulsion has altered the design. In the same way there is a fundamental difference between a keyboard transmitter and a typewriter, in the fact that the energy for printing the character has to be provided by the typist, whereas the keyboard transmitter key has merely to direct certain operations. I hope that the author will design a keyboard on the lines which he has suggested. With regard to the receiving mechanism, it is gratifying to be able to state that a British machine has been adopted by the Post Office, and is giving admirable results in practice. Some essential parts of the mechanism common to all successful machines were invented by Baudot. The Grünenwald plan [section (4)] is interesting but unlikely to be of service in this country, since the 5-key method of sending may be regarded as obsolescent owing to the fact that its speed is definitely less than that of a tape-controlled transmitter. The regenerative repeater, which we owe to the genius of Baudot, constitutes a notable advance, and a combination of the regenerative repeater with the Gulstad relay enables large economies in staff to be effected. It increases the working speed and stability of the circuits whilst giving remarkable flexibility in the extension of the various channels. Multiplex and voice-frequency systems consist merely in methods of economizing line plant, and it is only over very long distances that the cost and complexity of such methods can be justified. It has been demonstrated that an infra-acoustic circuit can be added to any telephone circuit without appreciable reduction in the telephone speaking efficiency. This means that a comparatively indefinite number of telegraph channels are available and the obvious development of the future seems to lie with these circuits, to which will be added some method of automatic switching so that retransmission of messages is entirely avoided. It is only when the source of supply of such channels has been exhausted that methods of multiplex operation of circuits can have any field for application. This excludes the case of the transoceanic cables, where the annual charges on the cable form the bulk of the cost incurred in the transmission of a message. The Creed quadruplex and the author's Morse multiplex are interesting examples of what can be done by the mechanical connection of two transmitters, but it is difficult to see that this method can at present be utilized in practice. The method of eliminating the "jar" on duplex circuits should go a long way towards solving the problem of duplexing loaded cables, and I should be glad to learn whether experiments are now in progress to exploit this suggestion. The interlinking of start-stop systems with duplex multiplex circuits is interesting, and may conceivably have considerable application when the possibilities of infra-acoustic circuits have been fully exploited. I am driven to the conclusion that the future of inland telegraphy will be bound up with the question of the transmission of communications direct from subscriber's office to subscriber's office. It may be that this development will take place by a comparatively gradual process, and that we shall first have a large number of leased infra-acoustic channels connecting firms having large amounts of business to transact together. The advantages of rapidity having been appreciated, the next stage in the development would be an automatic form of switching from any subscriber to any other subscriber furnished with suitable apparatus. The dawn of this era depends not on engineering advances, but solely on what is generally called "salesmanship" in the commercial world. In view of the difficulties which the manufacturers of calculating machines must have had to overcome in order to persuade the ordinary conservative business man to adopt their methods, it is clear how difficult a problem will be involved in making that same business man realize the advantages which will result from greater rapidity in his work. I should like to emphasize the point that the advantage of the direct telegraphy method over the telephone call lies in the fact that the written telegraph message can be dealt with in a routine manner in the office of the recipient, whereas a telephone call is frequently made either to the wrong department or to a person to whom the detailed knowledge necessary for an instant reply is not available. I think that the telephone should be used where discussion is necessary, and that for a vast volume of business at present conducted through the medium of the post the greater celerity of direct written communication would be of definite economic advantage.

Mr. F. G. Creed: I am glad that the author refers to the difference between the conditions which obtain in this country and those in the United States, and to the reason why the telegraph has a greater vogue over there than here. In favour of the Post Office it must be admitted that conditions which do not exist in America have to be faced in this country. With regard to the Mendonca governor, it seems to me that this is a British invention, as I believe that one of these devices was used on the Evershed and Vignoles megger many years ago. I invented it myself independently, but when about to use it I discovered that it had been anticipated. I think, therefore, that this governor should be given another name. The conflict between the Morse Code and the 5-unit Code is not yet settled, but it has come to be recognized, I think, that for the bulk of inland traffic and for a great deal of international traffic the 5-unit Code is the more generally useful, because it is so adaptable. Morse, however, will still be widely used on account of its remarkable flexibility. A Morse or a Wheatstone apparatus is ready to work as soon as it is placed on the table, and no adjustment of any kind is necessary. This cannot be said of the 5-unit multiplex apparatus, but 5-unit equipment of the start-stop type more closely approaches the Morse system in flexibility and reliability. The 5-unit system has made numerous advances which have made it easier for this system to become successful. There has been great improvement in lines in the principal countries of the world, battery conditions have improved and there has been a still bigger advance in apparatus—especially in relays and apparatus connected with synchronism. Practically perfect synchronism can now be obtained without any difficulty, and there is a choice of half a dozen pieces of apparatus to provide synchronism for the purposes of start-stop. As the author points out, regeneration has made another surprising advance, and a message can now come to London in two jumps from Rio de Janeiro. It comes through by regenerative repeaters across the Andes and up the west coast of South America to New York in one jump, and it reaches New York a fraction of a second after leaving Rio de Janeiro. The next jump is through several repeaters to London, and this takes place with equal rapidity. The present-day achievements of the telegraph are remarkable. When in India two years ago I arranged to have telegrams sent to me from distant places, one from Vladivostock in Siberia, another from Copenhagen and others from London, New York, San Francisco, Buenos Aires, Sydney (Australia) and Hong Kong. I asked that the telegrams should be dispatched to reach me in Bombay at 9.30 on a certain morning. They arrived with an average delay of half an hour, and I do not suppose that any particular care was taken to hurry them along. Unfortunately, however, the telegrams took an hour and a half to get from Bombay to Delhi, where I was demonstrating. This was all done by morse. Except for cable and radio services, the great bulk of telegraph work will, I think, in the future be handled (until something better is produced) by the 5-unit or 6-unit Code and especially by the start-stop apparatus, along the lines suggested in the paper. In my opinion, however, the telegraph engineer will have to consider more carefully the question of a 6-unit as against a 5-unit Code. The 5-unit Code only gives 32 combinations and of these a great many have to be used for shift, line change, column feed, etc., so that it is as much as one can do to obtain 26 useful combinations. Only about 45 letters and signals are commonly necessary in ordinary telegraphy in most countries, but with the 6-unit Code a total of 64 combinations is always available without any loss of time in shift. I think that it would pay even now to adopt the 6-unit system instead of the 5-unit, in view of the enormous development which in the future is bound to take place in connection with printing telegraphs. The author regards distance and time difference as the principal factors governing the use of the telephone in preference to the telegraph, but I would suggest that there are other factors of equal importance. As Mr. Herbert has already pointed out, people's time is valuable, and every year the value of time is growing, the cost of living is rising and we have to increase wages and salaries. Business men who have important engagements all day long do not wish to be interrupted by the telephone, and it would therefore be much better to have something that will produce a printed message. The question of language is also of some importance. In my own case, for example, while I cannot speak French fluently enough to hold a conversation over the telephone, I can write it sufficiently well for the average Frenchman to grasp my meaning. Tele-writing would facilitate the communication in both directions.

Lieut.-Col. A. G. Lee : With regard to the remarks on page 1376 concerning the control of tuning forks, the author attributes the invention of the valve-maintained tuning fork to the Western Electric Co., but I believe that it was invented by Eccles and Jordan, who took out a patent for it during the War. The valve-maintained tuning fork has been investigated by Dr. Dye at the National Physical Laboratory, as well as by others, and a considerable amount of work has been done on the subject. We employ a valve-maintained elinvar tuning fork at the Post Office Rugby Wireless Station, for developing the frequency used in the transmissions. We start with the valve-maintained fork oscillating at about 2 000 cycles per second and take harmonics from that to produce the frequency required. The advantage of the elinvar fork is that the temperature coefficient is practically nil. One of the factors which determine the constant frequency of the valve-maintained tuning fork is the same as that which gives constant frequency in a valve oscillating circuit, i.e., the grid and plate voltages must be as nearly as possible 180° out of phase. This condition is obtained by a suitable arrangement of the circuit, and since the tuning fork is then independent of any other factor such as the battery voltage the system oscillates at the frequency of the fork itself. By due consideration of factors of this type and by the use of thermostatic regulation, the Marconi Co. have produced a steel tuning fork which has maintained a constancy of frequency of 1 part in 100 000 for 7 months without any synchronizing whatever. The B.B.C. also use steel tuning forks at some of their small stations from which the harmonics are obtained in a way similar to that in use at Rugby. By this method the frequency of the wireless transmitter is maintained constant, it being necessary that these stations should keep within 5 cycles of each other and at a frequency of the order of 1 million cycles per second. The B.B.C. have, I understand, maintained this frequency within 5 cycles throughout the last two years. The steel tuning-forks both of the B.B.C. and of the Marconi Co. have a thermostatic control which regulates to within ± 0·05 deg. C. I think that such arrangements, although perhaps rather elaborate for an ordinary telegraph office, might, as the author suggests, be justified for those of the largest type. On page 1381 it is stated that the speed control of a number of synchronous motors in one office is quite practicable and that its advantages require no emphasis. I agree with the author that the advantages are considerable, but where the out-stations are in different countries and in different hands I think one control for the whole office is likely to give some difficulty. With reference to the Verdan system described on page 1423, this is the modified Baudot apparatus which, it is claimed, will remove to a large extent the effect of atmospherics in radio circuits. The arrangement was invented some time ago, but its use has not become widespread for a reason which is evident from the table on page 1423, in which the method of operation of the circuit is clearly set out. From this table it would appear to be only necessary to go on repeating a signal a sufficient number of times in order to eliminate the atmospheric disturbances. This supposition, however, overlooks one fundamental point with regard to atmospherics—they do not always reinforce the signal, as suggested in the first column of page 1423. When an atmospheric causes a free oscillation in a radio circuit the oscillation lasts a considerable time—of the order of a dot or a dash and sometimes longer. If the atmospheric disturbance occurs at such a time as to produce a phase difference in opposition to the signal element in the circuit, the effect of the latter is completely swamped, as is borne out by practical experience. Also on short-wave circuits there is fading or partial disappearance of a signal, a phenomenon which occurs probably to an extent equal to that of the atmospherics. I would estimate disturbances due to fading at 50 per cent, and disturbances due to atmospherics at 50 per cent, but the Verdan system will not deal with fading. With regard to phantom working, we have in this country a large number of telephone wires and we are at present experimenting with double phantom working: this is sometimes known as "ghost working," and is referred to in the paper. It makes use of a circuit which is superimposed upon telephone phantom circuits, and by its aid we hope to obtain for telegraphic use a large number of circuits which cannot be used for telephonic purposes, thus allowing teleprinters to be installed in place of the Baudot system. Experiments have recently been carried out in connection with the loading of double phantom circuits. It was evident that since the circuits were being used for telephone purposes, loading coils for telegraphs could not be inserted directly in the lines. At points 50 miles apart where these circuits entered telephone repeater stations a loading coil was introduced, and it was found that by concentrating the loading at these points it was possible to work the teleprinter apparatus on such underground telephone circuits. With loading we have worked over a distance of 600 miles without a telegraph repeater in circuit, whereas when the loading is omitted we can only work over 200 miles without a repeater. Regarding a telegraph current as being of the alternating type, it can be represented by a low-frequency current of 25 cycles per second together with an allowance for the higher harmonics, say, up to 60 or 70 cycles per second. It has been found by experience that an allowance of this kind enables a received current which approximates to a square-topped wave to be obtained. The highest frequency—60 or 70 cycles per second—is comparatively low, and the spacing of the loading coils 50 miles apart enables us to obtain about $2\frac{1}{2}$ to 3 coils per wavelength. A value of between 3 and 4 coils per wavelength is usually necessary for telephonic frequencies.

Mr. K. L. Wood : The paper will be of great use in educating the young telegraph engineer and in broadening his outlook, which is liable to be restricted to the system with which he is particularly concerned. With reference to the first paragraph of page 1372, I should like to point out that the mechanical hit-or-miss method of selection (on the gas-engine governor principle), employed in the Heurtley and the Eastern Telegraph Co.'s systems of cable regenerators, appears to approach as closely as possible to the theoretical desideratum of an infinitely small receiving segment. I do not know whether a comparison has ever been made between the mechanical system and that in which picking-up and locking relays are controlled by a brush passing over a short segment on a distributor. It may be that, while the mechanical system is nearly perfect, the electrical one is so nearly as good that the difference is not apparent in practice. It would be interesting to know whether the method for overcoming possible distortion due to indefiniteness of the commencement of the regenerated signal owing to the breadth of the pick-up segment, which was the subject of a patent, has been found to be of any practical advantage. With regard to the correction of a reed or fork by reference to a clock (pages 1377 to 1380), it would appear at first sight that there is little difference in principle between the methods of Figs. 13 and 14. It will be noticed in Fig. 14, however, that when the correcting mechanism AM or RM rotates the shaft S in one direction or the other, and alters the speed of the reed R by an alteration in the angular relation of the magnet M to the armature at the end of R, then, since the commutator C is on the same shaft, its angular position in relation to the brush B at any time is altered. This phase alteration of the means of comparison is the principal feature of the invention, and it is very important in that it prevents hunting. This would inevitably occur with the arrangement shown in Fig. 13 unless the phases both of the commutator and the clock contact were correct and the reed had the right speed at the moment of starting. For example, suppose that one were timing a clock to a standard chronometer by making observations of the hands at intervals and altering the pendulum of the clock to be corrected only; if the hands showed a fast error a losing rate would be put on until the positions of the hands had been made to coincide. The chances are that when this occurred the rate would be too slow, the hands would fall behind those of the standard clock and an oscillation of the speed and hands would take place. Alteration of the commutator C in Fig. 14 is seen to be equivalent to making a step alteration of the hands every time a correction is made to the pendulum, and it is by this means that hunting is avoided. With reference to gang driving of motors (page 1380), the number (8) of motors controlled by one reed is small. We have found that each reed can control 4 relays, and since each relay normally operates 3 motors 12 of the latter can be run from one reed. This is a convenient number and the reed and relay contacts do not give any trouble in these conditions, it being possible to run 20 motors without evidence of undue sparking. Further, it is possible to control a second reed from the first by the simple expedient of connecting the driving magnet in series with that of the controlled reed, the reed being so adjusted that its natural period is nearly correct. In addition to the advantages mentioned in the paper it may be stated that, since at every station on a chain of regenerator stations the motors are running at the same speed within the accuracy of the various clocks, changes of speed can be made with little trouble. Each station is provided with numbered gears which are easily interchanged, and it is only necessary to change the gears on the transmitter and on the regenerators at intermediate stations in order to increase or decrease speed by a definite amount. All hand adjustment of the speeds of the various reeds is eliminated, and there is no need to wait for the stations nearer the terminal to synchronize before further stations are readjusted. Circuits can be, and often are, stopped at a given time, the speed is altered, and traffic is passed on again at the altered speed within half a minute with 4 synchronous stations on the line. The number of stations makes only a slight difference to the time taken to regain synchronism since the whole operation, beyond changing a pair of wheels, is automatic. It seems to me that methods which have been found to work so successfully as this could be applied to the stop-start system. It is interesting to know that both backward and forward corrections were used in the Baudot original method of correction. For submarine cable regenerator systems employing a number of linked sections this method is essential. The remarkable rapidity with which a series of 22 cable regenerator stations can come into synchronism after a change of speed, or on starting up, would not be possible on one-way correction; to those accustomed to the equal-speed 2-way correction system, it is a matter of surprise that a system demanding continual corrections to enable one station to keep phase with another whose speed is different, does not, even on landlines, produce disadvantages out of proportion to the simplification of the apparatus. Cable distortion due to balance and other factors causes the arrival time of the signals to differ considerably, and the greater the interval between the times of arrival the greater the phase shift must be in order to pick up sufficient corrections to compensate for a change of speed. In this respect there is a fundamental difference between synchronizing on submarine cables where distortion is present, and synchronizing on landlines where distortion is comparatively small. With reference to Fig. 30, I should like to mention that this apparently somewhat crude mechanism was devised in 1912 and there was a good deal more on the shaft behind the disc which carried the 4 rollers, than is shown on the diagram. I aimed at producing a sleeve capable of being easily corrected whilst rotating, but in which the corrected part would be rigidly attached to the shaft when the cams were called upon to do serious work. In addition to the phase correction, step-by-step speed correction acting on the governor adjustment shaft was used. The method of Fig. 37, for altering the rate of the reed itself in accordance with the impulses derived from the signals, is a good one, but it necessitates a separate reed for each regenerator set. The clock control method, therefore, is more economical.

With reference to the start-stop mechanism described on page 1393, the early cable clutch regenerators worked on this system, but it was soon realized that errors in starting (due to distortion) and in completion of a letter (due to speed) resulted in the mutilation of the space element, and that the latter was just as important as a signal element. A method for limiting the effect of distortion was devised, but it was found that each step in this direction necessitated a more and more accurate speed. The natural result was that in 1914 we turned our attention towards developing a continuous rotary system, but no progress could be made until after the War. With reference to speed and phase indicators (page 1397), close setting by the clock of the reeds at stations and the use of gearing from a constant-speed motor obviates the necessity for these devices on cable code working. With regard to phase orientation (pages 1397 and 1398), although the method due to Higgitt of rotating the stator of the motor is mentioned in another part of the paper, it might have been included in this section where such methods are classified. It is ingenious and has the great advantage of eliminating gears and their attendant backlash. No mention is made in the paper of converting transmitters, in which cable code is sent to line from Wheatstone slip, or of perforators, in which Wheatstone slip is produced from cable code signals. As regards clutches, no reference is made to that successful type in which there is very little friction when it is not operated but the operative member of which when released is clutched to the rotating shaft in such a way that increased work on the clutch gives increased frictional grip. Such clutches can work at high speeds and can grip with an accuracy of $1\frac{1}{2}$ per cent of a revolution at, say, 1 000 r.p.m. The description, on pages 1433 and 1434, of the automatic scrutinizing device employed by the Eastern Telegraph Co. deals chiefly with its use for indicating the introduction of bias, but this is only one of the useful features since it will indicate deterioration of the signals beyond a certain predetermined point, due to any cause whatever; this point is set so that warning may be given before such deterioration occurs as will give rise to occasional errors. The synchronizing system adopted by the same company, in which phase corrections may be applied in either direction, enables a bias-correcting system to be used which depends upon the early or late arrival of the signals due to bias. For instance, if in a cable code system the dots produce a greater number of early corrections than late and the dashes a greater number of late than early, it is obvious that the dots are thick and the dashes are thin, i.e. a dot bias exists, and vice versa for a dash bias. Since the correcting relays indicate early or late and the line relay shows dot or dash, it is possible to work a ratchet mechanism attached to the relay bias-adjustment so that it is operated in one direction or another until the bias is eliminated. This step-by-step system is found to be very reliable.

The transposing system of the Western Union Co. (Fig. 125) for passing double-current Wheatstone signals over a cable as positive, negative and zero signals is ingenious, but the speed loss would be about 30 per cent compared with ordinary cable code. What might be called a " contrary " transposing system was devised for the Eastern Telegraph Co. in 1925; it enables ordinary cable code signals to be relayed through a land line working double current, i.e. with positive or negative always on. This system, which has since been improved, shows on land lines a 30 per cent gain in speed possibilities as compared with Wheatstone working, although it is probable that in most cases such a gain would not be important. With regard to page 1439, I should like to know what results are obtained with the duplex " jar " eliminator. When a sending inductance is used we should not expect much, if any, benefit to be obtained. The inductance smooths off the rate of change of the sending current, and we therefore consider that in general the majority of the balance disturbance does not take place in a particular small part of the sending period. Unequal channel working receives no consideration in the paper, although it is coming into use to a certain extent where two cables of different *CR* values are linked up to a high-speed cable, the high-speed cable carrying two channels of different speeds, and the regenerator at the junction retransmitting the faster channel into the low *CR* cable and the slower channel into the high *CR* cable. This system involves the selection of signals from a regular-running instrument such as a transmitter, so that the signals can be selected regularly and sent irregularly on the transmitting side whilst on the receiving side they are selected irregularly and sent regularly. With regard to the saving of staff by the introduction of machine switching, this has been done as far as possible on cable networks by arranging selective switches at each intermediate station on a regenerator chain. These switches give great flexibility, enabling a terminal to drop messages automatically at any intermediate station in the form of perforated slip for use in a printer or for retransmission on branch lines. They also allow any station to transmit to any other station on the unoccupied part of the chain, or when the terminal is pausing. Owing to the smaller number of lines there is not nearly so much scope for economies of this kind on cables as there is on an inland network.

Mr. W. Cruickshank: In connection with 2-way working on loaded cables (pages 1440 and 1441), the author states: " If wave pulses are sent from both ends simultaneously, the electromagnetic pulses meet somewhere in the cable and two cases arise as shown in Fig. 127(*b*)." The first case is where two positive e.m.f.'s are applied, one at each ene of the line, and the second is where a positive e.m.f. is applied at one end and a negative at the other. It is further stated that "at coalescence either a doubled electric field or a doubled magnetic field is produced and this breaks up into two pure waves proceeding to the two terminals of the cable." I do not understand what is meant by pure waves, and with regard to the statement that pulses can be sent simultaneously from both ends of the cable and that "they will pass each other en route without interference," I think that the passing of two pulses on a cable is not possible without interference, if at all. In the case of two positive e.m.f.'s, fed one at each end of the line, it would seem that momentary currents or pulses start from both ends and that when such pulses meet at the centre the magnetic portion of the field disappears, its kinetic energy reappearing as potential energy at the end of the period. This may be the doubled electric field referred to by the author. The e.m.f.'s having been cut off and the receivers replaced at the end of the line, the two halves would discharge back through the receivers and give rise at each end to signals which are really produced by their own pulses, the phenomena being somewhat similar to particular cases in the ordinary differential duplex. In connection with Fig. 129(*b*), the author suggests that it is possible to use such an arrangement as a phase corrector, and on page 1441 he describes the same arrangement as an example of successive differentiation carried out on a network of shunt and series impedance. He states that the voltage across inductance L_1 is $v_1 = L.di/dt$, where i is the arriving current, and that this voltage applied to condenser C_1 produces a current $i_1 = C_1.dv_1/dt = C_1.d^2i/dt^2$. Although this may be mathematically correct the fact remains that the voltage v_1 is not the one which is applied to the condenser C_1. The circuit shown in Fig. 129(*b*) is merely a high-pass filter. I agree with the author as to the means which he has suggested for turning the loss on telegrams into a gain. The only hope of making inland telegraphs pay lies either in arranging for the public to send the telegrams themselves or in reducing the number of retransmissions. The former scheme could be put into practice (as in the case of telephony) by an operator at the sending station manipulating a dial for the purpose of selecting a distant office. The system of Fig. 139 would be suitable, and although a complicated machine telegraph and a rather complex telephone mechanism are involved both have been shown to be satisfactory, and it is only a question of applying the two together to make the scheme successful. It may be a paradox that in order to make the telegraphs pay the number of lines must be increased, but the line costs of the telegraph administration form only a small proportion of the total cost. The major item of cost of inland telegraph traffic is the operating expenditure and it is only by reducing the latter, even at the expense of increasing the size of the line plant and the number of channels, that a way out of the present position can be found. Colonel Lee has spoken of the method of working double phantom circuits, and Fig. 122 shows a German scheme for working telegraph circuits on telephone pairs. This diagram, however, does not give a full account of the system and one difficulty in connection with superimposing telegraphs on telephone pairs is the lack of space at the repeater stations. In order to send low-frequency telegraph signals and allow them to pass the telephone repeater, a low-frequency pass filter has to be adopted. This by-passes the telegraph currents round the telephone repeater, the current reappearing on the down side of the repeater. At a repeater station it is a very simple matter to by-pass the telephone repeaters, provided that a telegraph circuit is superimposed on the phantom telephone. As Colonel Lee has mentioned, we have been working London to Glasgow satisfactorily for 2 months with loading coils at the repeater stations only, and the teleprinter has been used without any trouble whatever. The currents on this line are of the order of 1 mA per wire and 4 mA per quad, their amplitude approaching that of telephone currents. It is possible to work the telephone circuits without noticing the telegraph signals at all.

Mr. H. Kitchen: Large telegraph offices are becoming more and more dependent upon a power supply, and any failure of this supply creates an abnormal amount of trouble and dislocation of service. For example, recently when a dense fog came over London all the lights were switched on and the voltage dropped appreciably, with the result that the Central Telegraph Office, so far as the motor-driven portion of it was concerned, came to a standstill. Now that the country's electricity supplies are being changed over to a.c. we are likely to experience more trouble than has been the case with d.c. motors, because a.c. motors capable of running at a constant speed do not seem to be freely available and when they are procured are not entirely free from trouble. I should like to ask the author whether in running a.c. motors with telegraph printing mechanisms he has experienced any trouble due to excessive heating. Mr. Cook of the Post Office has designed a governor for use with Baudot distributors and this is working very satisfactorily. This governor is more easily adjusted and handled than the standard Baudot governor. On page 1376 there is a list of external factors which cause variations in the rate of vibration of a fork or reed, and to this list I should like to add mechanical vibration. Care should be taken to select the most stable position possible for a tuning fork or reed. On page 1419 the author states: "The capacity of a duplexed line is only $1\frac{1}{2}$ times its simplex operating speed as a maximum"; this statement, I think, requires some qualification. The longest and most difficult Baudot circuit in this country is the underground line between London and Newcastle, which is working quadruple-duplex. If this circuit were worked simplex the capacity would be about 50 per cent of its present value, and I think that this percentage might be applied to the majority of hand-worked systems. On page 1451 the author gives his views on the problem of retransmission of messages and indicates that the solution lies in machine switching and machine telegraphy. Machine switching has been tried by the Post Office, but not precisely as suggested by the author. The experiment has not been very successful from the traffic point of view because, although fewer operators may be needed in transmitting telegrams from A to D, where there are two intermediate offices, so much time is lost in dialling and getting through to the particular station that the effective load of an operator drops from about 72 to 28, and therefore approximately 50 per cent more operators would be required to work such a system. Expensive machines such as teleprinters should not be supplied to offices where the load is comparatively light, and offices with heavy loads should not be joined to a concentrator or to a machine switching arrangement, if the maximum economical advantages are desired. Machine switching causes excessive delay, and as rapid despatch is the first essential of a telegraph service it is not clear how the proposal could be applied without considerable additional cost. I am afraid, therefore, that application of the author's ideas would not lead to a reduction of costs. Some other method, I think, will have to be devised and this is really not so much an engineer's as a traffic officer's problem.

(*Communicated*): At the author's suggestion I give below a brief description of the Cook type of Baudot governor (Fig. A). This modified form of the Baudot governor was devised to permit of speed alteration directly by means of a screw motion, and without the use of additional masses. It also gives a wide range of speeds without the necessity for experimental adjustment as regards initial spring tension. Adjustments for speed are effected by altering the length of spring in use, and the basic requirement of zero tension at zero amplitude is maintained automatically once the governor has been assembled correctly. The single mass of the Baudot governor is retained, but only one spring is employed, one end being anchored to the mass and the other supported by a blade passing between the spirals of the spring. The spring can be rotated at its point of anchorage in the mass in order to fix the correct tension at assembly and should not thenceforth be altered. The blade is a fixture at one end of a cylinder and corresponds in effect to the potence of the Baudot governor. The other end of the cylinder is threaded and screws into the frame of the governor, the pitch of the thread being the same as the spirals of the spring and both being right-handed. By turning the cylinder clockwise, the blade is advanced along the spirals of the spring, and, although the effective portion of the spring is shortened by the process, no additional initial tension is given because the blade and cylinder have together been moved across the centre of rotation by an exactly equivalent distance, the cylinder being screwed into the frame. The speed is now higher than before, but the balance of the governor as regards tension is undisturbed and is correct for the whole range of movement which the thread and spring permit. It is essential that the spring be so wound that it is without tension when fully collapsed, or alternatively that the pitch of the thread cut on the cylinder is proportionately reduced if such initial tension exists. The range of speed given is approximately 165–195 revolutions of the brush arm per minute, and the accuracy of the governor does not vary appreciably from that of the standard pattern.

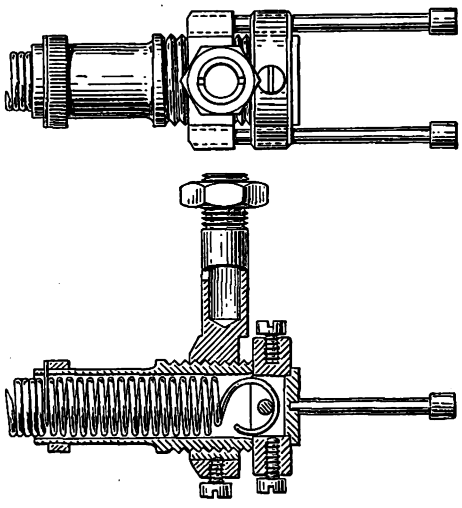

FIG. A.—Cook's Baudot distributor governor.

[The author's reply to this discussion will be found on page 1464.]

NORTH-EASTERN CENTRE, AT NEWCASTLE, 10TH MARCH, 1930.

Mr. F. G. C. Baldwin: It is pleasing to note the author's tribute to the work of Baudot, and although his system must eventually be abandoned, Baudot's work will stand as a monument for all time. The author gives sound reasons why the telegraph is more successful in America than in Europe. I think that similar reasons apply in regard to telephony. While I am hopeful of increased development in the use of the telephone in this country, and I agree that there is plenty of scope for further development, the fact cannot be disguised that comparisons between this country and America which do not take into consideration the geographical differences of the countries and the temperamental differences in the people, are futile. The author's suggestion for avoiding retransmission by the adoption of machine switching is interesting, and there may be places where such provision could be introduced. Reference is made to what, I think, would prove to be the chief difficulty, viz. the congestion arising in busy periods between places with one or only a few outlets. One station might call another unsuccessfully at intervals and still not dispose of traffic in a reasonable time during peak hours. Machine switching would not allow of code time working. Similar methods were tried by the Post Office and the results were not an unqualified success. It seems doubtful as to whether the automatic switching scheme suggested in the paper would be sufficiently flexible. The difficulty is that the telegraph is not developing in the same way even as the telephone. With regard to motor speed-control, it is agreed that constancy of speed is essential, and the Post Office has had little difficulty with d.c. motors. Alternating-current supply is now becoming common, and difficulty is being experienced in obtaining a.c. motors which run at a constant speed. Has this difficulty come to the author's notice, and does he know of a method whereby it can be overcome? Mr. Cook, of the Post Office Telegraph Department, has devised a governor which is functioning excellently on Baudot sets and which is simpler and more easily handled and adjusted than the standard Baudot governor. Regarding vibrating reeds or forks, the experience of the Post Office is that voltage variations and mechanical vibration are the cause of most of the trouble. An appreciable drop in the power supply to a large telegraph office is responsible for a general stoppage on all power-driven units, with consequent delay and confusion to traffic. After reading the paper, the power engineer will appreciate the difficulties of the telegraph engineer in maintaining synchronism. Vibration is difficult to avoid, and the utmost care should be exercised in choosing positions for forks and reeds. Twelve teeth are shown on the star wheel of Fig. 26; the Post Office uses a wheel with 15 teeth, and this reduces the amount of phase displacement.

Mr. J. W. Wilson: As a Press telegraphist I should like to give some account of the use of the telegraph so far as newspapers are concerned. The Press of this country is indebted to the telegraph, and also to the telephone, for the supply of more than 50 per cent of its news. Generally speaking, newspapers are purely business propositions and if they are to make a profit they must supply their readers with fresh news, in order to create and retain their circulations. As an example of the amount of news telegraphed in connection with an up-to-date provincial newspaper, I would mention that the *Newcastle Chronicle*, which was the first newspaper in the country to have its own private telegraph facilities, receives between 80 and 100 columns of news daily over its system of five wires, viz. from London, Glasgow, Manchester, Middlesbrough and the Press Association. Several columns are also transmitted from Newcastle to other offices in the Allied Press group, and the total traffic exceeds 100 000 words per day. Since all the newspapers throughout the country are collecting and transmitting news in this way, it can readily be seen that the telegraph system plays an important part in the organization of newspapers. Press telegraphists unfortunately have little opportunity for experimental research, as they have to concentrate on the practical side of their profession. Newspaper proprietors are not concerned with the advantages of one system of telegraphy over another. Their first consideration is economy, their second is efficiency and their third, and most important, is speed; the system which provides these three essentials is, to them, the ideal one. It was chiefly the question of speed which decided the very existence of newspaper private wires, and as soon as these had been introduced it was found that "copy" was being received much more speedily than before. Test messages were occasionally dispatched over both systems at identically the same instant, and in every case the newspaper private wire was found to be faster than the public service, even by such a margin as 2 hours between London and Newcastle. In view of present-day competition speed is more important than ever, and every second is of the utmost value. During the last decade the advance in Press telegraphy has been almost revolutionary. A little more than 10 years ago there was not a newspaper in Newcastle which possessed any mechanical means of telegraphic communication other than the Wheatstone apparatus, the key and the sounder. At the present time the entire Press of the city is mechanized, and the Creed system, which has completely justified itself for this class of work, is used—as it is in the case of the majority of newspapers throughout the country. The Baudot, I think, is to be preferred for commercial purposes, but for Press work it must be acknowledged that the Creed system with the column printer is the most economical of all systems of high-speed telegraphy. It is, in fact, the best one-man equipment in existence. Newspaper authorities are now realizing the vast importance of their telegraph systems, and are regarding them more and more as the pulse of the whole organization. Without an efficient system of high-speed telegraphy no newspaper can hope to exist, and a breakdown in the telegraph means chaos in every other department. During the last year or so the Allied Press have provided Messrs. Creed and Co. with opportunities for experimental work on their wires between London and Manchester, and as the outcome of these experiments the system at present used by the Allied Press group will doubtless undergo considerable change in the near future. I am unfortunately not at liberty at the moment to give any information as to the methods to be adopted, but some of the apparatus upon which the author has commented favourably will be used to speed-up the telegraphs of the Allied Press. The regenerative repeater is doing much to speed-up telegraph communication, but those responsible for Press telegraphs are slowly—though nevertheless surely—beginning to favour the use of the thermionic valve, with its untold possibilities. The Press is just beginning to feel the necessity for development in its telegraph service, and attention is being focused more and more every day on the possibility of development through the medium of the "picture" cable, the idea being that a perfect connecting link between two distant stations leads to considerable improvement in the speed and reliability of all systems. The introduction of phototelegraphy as a commercial proposition has provided a new field for research, and with such remarkably efficient cables as those now used for the purpose of transmitting pictures one is at a loss to imagine the future possibilities of telegraphy. At the moment, excellent pictures are being received from such distant centres as Brussels, Paris, Lugano and the Riviera. The results of these transmissions are quite as good as those from comparatively near centres such as Glasgow and Manchester, and it is in this direction that the Press expects future development to take place. The change-over to the "picture" cable may not come for some years, although we have been experimenting in this direction with some measure of success. In addition I understand that experiments conducted by the Post Office have been carried even further with equal success, and with the introduction of several different frequencies the old multiplex systems will have to be overhauled and brought up to date. The advance of telegraphy calls for an equal advance in technical knowledge on the part of all telegraphists, whether they be employed on a newspaper or elsewhere. The old-time key-and-sounder clerk is dead, and the operator-telegraphist of the future will have to be a more skilful as well as a more intelligent individual than his predecessor. In this connection I advocate compulsory training in technical and mechanical telegraphy for all young men and women who aspire to become telegraphists.

Mr. J. T. Bramwell: I was surprised to read on page 1419 that the traffic-carrying capacity of a Baudot circuit is not doubled where duplex working obtains. On making inquiries, I found that in one hour this morning 173 messages were forwarded and 222 received on a certain duplexed Baudot circuit; more messages could have been disposed of had they been available. Had this circuit been worked " up and down " or simplex less than 197 messages would probably have been transmitted, as time is lost in the gumming process. I suggest that in practice duplex working does double the traffic-carrying capacity of an inland Baudot circuit, and I should be glad if the author would verify the statement referred to. The evil effects of " bounce " and transit time are mentioned on page 1426, and on the following page the merits of the Gulstad relay are set forth. The line relay LR in Fig. 112 appears to be of the ordinary type, without any provision for counteracting these two unfavourable characteristics, and yet the combination of relays in Fig. 112 is described as a true regenerative repeater. As " bounce " and transit time are almost non-existent in the Gulstad relay I suggest that better results would have been obtained had one of these been used as a line relay. Will the author give his views regarding this suggestion? With reference to the financial loss on the inland telegraph system, I think that the extended use of teleprinter apparatus and the utilization of cable wires jointly for telephone and telegraph purposes will help to solve this problem. The author's forecast of automatic telegraph systems similar to present-day telephone systems will no doubt be partly, if not wholly, realized in the course of time. In the meanwhile, however, I consider that economies could be effected by introducing through switching facilities on telegraph concentrators at centres such as M in Fig. 139. With a view to reducing the number of retransmissions, circuits fitted with start-stop apparatus might be advantageously terminated on concentrators at large centres, and where phantom circuits can be formed they too might be terminated on concentrators as through switching outlets. Regenerative repeaters and cable-code calling and clearing signals would probably be found useful in the development of such a system.

Mr. G. F. Bellwood: In reading the paper I have been impressed with the following two definite features. First, that the electrical condition of the circuit must be perfectly stable in order that the printing mechanism may function correctly; secondly that, generally speaking, printing systems are comparatively slow, and where speed of transmission above a certain number of words per minute is obtained there is no individual printer which will work at the same rate. In support of the first statement, numerous examples are given in the paper relating to synchronism, corrections, governors, phonic wheels, speeds, etc., and the arrangements adopted to secure a satisfactory electrical condition are explained. With reference to my second comment, it is necessary to multiply the number of printers in order to deal with incoming traffic. For example, in the Creed system a speed of 200 words per minute may be obtained, but the printer can only work at about 90 words per minute, and hence at least two printers would be necessary to carry the traffic on a fully loaded circuit. As a further example to illustrate the slowness of the present printing systems, I would point out that some years ago it was usual to work a Wheatstone telegraph over a distance of approximately 200 miles of aerial line at an average speed of 550 words per minute. The transmitter and receiver both had specially weighted driving motors, and at the receiving end a polarized relay of 400 ohms resistance was placed directly in the line circuit, the Wheatstone receiver being worked from the relay local. The received tape slip was written up by hand, but if Creed printers had been available it would have been necessary to employ about 6 of these to keep pace with the Wheatstone transmitter. In the Baudot and stop-start systems transmission speed and printing speed are identical, and each channel clears its own traffic; the " Autoplex " also prints at the same speed as that at which the transmitter works, and this is an advantage. The process is thus carried out in one step and additional staff and instruments are not required. In order to make for economic efficiency each channel should clear its own traffic, but in all machine systems where each channel completes its own work speed is lacking. Our printers are not by any means high-speed instruments. The fastest and most modern which we have in use, the " Teleprinter 3A," is a start-stop instrument developed by Messrs. Creed and Co. This gives an actual speed of 60 words per minute, and each channel completes its own traffic. We must apparently remain satisfied with this speed, for the following reasons: (1) Operating costs are low, and a skilled Morse telegraphist is not required, although in this connection experience counts. (2) The speed is of the magnitude with which the average typist can deal and within which the existing staff may be trained to work. Fig. 122 shows a system of sub-audio telegraphy on a normal telephone loop, and it would be interesting to know whether the ordinary Post Office method of superposing a telegraph on a telephone loop, or even of superposing a loop telegraph on two telephone loops, could not be efficiently adopted. In theory, the telegraph signals sent over the loop should cancel out, and a speedier and more efficient circuit than that shown in the diagram should be provided. The 2-power diplex signalling system with 5-unit code, shown in Fig. 123, is interesting, but I think that the last paragraph on the first half of page 1436 needs amplification, as in my view a diplex is a circuit which works two ways out and one way in. It is, in fact, an ordinary quadruplex with the " B " apparatus removed at one end, and in the duplex condition. I should be in agreement with the principles of the system shown in Fig. 139 if the proposed system were on similar lines to that in an automatic telephone area, with manually worked junctions and trunks for long-distance communication and zone working generally. Unfortunately for the telegraphs, however, local traffic within a radius of 10 or 20 miles is practically negligible, and only long-distance telegraph traffic would have to be catered for, except in isolated cases. The following disadvantages occur to me: (1) For short-distance traffic it is cheaper to use the telephone with its combined question and answer. A 3-minute conversation is allowed, as against a 12-word telegram. (2) The traffic from one of the regional offices, connected to the north centre, for example, may have telegrams for places as far distant as between 200 and 300 miles. I do not know of any dialling arrangement which would permit of signalling over such distances, even if circuits were available. (3) It is stated that the system becomes feasible because of the number of telegraph channels rendered available through the combined use of telephone-line plant for telephone and telegraph purposes, but even so, quite apart from the interference with the trunk circuit so far as signalling is concerned, at least one-third of the cost of a pair of wires should be charged to telegraphs in each case. For long-distance telegraph calls this would be very costly. (4) The time occupied in switching, especially over long-distance connecting lines, would be appreciable; in fact it might easily be as great as that occupied in transmitting, and this assumes that a free outlet is available. (5) The cost of the apparatus and maintenance of such a system would be considerable. The author has given us the genesis of a scheme which, although it has been mentioned before by other telegraph engineers, has distinct possibilities, though these may be more limited in scope than those which obtain in a telephone system.

[The author's reply to this discussion will be found on page 1464.]

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, 17TH MARCH, 1930.

Prof. E. W. Marchant: I am sure that this paper will be a classic in the records of the Institution. The subject with which it deals is highly specialized, and it is difficult for anyone who is not engaged in telegraph work to discuss it. I should like to refer to the governor shown on page 1372. This has, I believe, been in use for a considerable number of years, but, in the form in which it is shown, it is almost identical with a governor used by Mr. J. F. Gill in a speed indicator invented by him in 1915. I have here his patent specification. I understand that the author knows of an even earlier governor of a similar type. I should like to mention, however, that in the governor shown in Fig. 3 there is a brush bearing on the cone C; since the brush is rubbing against a cone it is almost certain that there will be uneven wear on the former, because the velocity is greater on the outer edge than on the inner. There is likely to be more wear on the outer side, and therefore the line of contact between the cone and the brush face may change slightly. Mr. Gill has improved upon this by using a pivot on the brush holder. This ensures that the radius of action of the force on the rubbing surface in relation to the pivot of the arms A_1 and A_2 remains unaltered with wear of the brush. The main advantages of the telegraph are that it can be used for very long distances and that a better load factor is possible with it than with the telephone. In the case of the telephone both the subscriber and his correspondent have to wait until the line is free, whereas with a telegraph the load can be spread out and better use can be made of the line. It seems to me, therefore, that the cost of a telegram ought to be considerably less than that of a telephone message.

Mr. T. E. Herbert: Speed and phase control is generally denoted by the term "synchronism." This term is scarcely applicable, for when we talk of two clocks being in synchronism we mean that both move at a uniform speed and that at every instant they indicate the same time, whereas two distributors are said to be in synchronism when their speeds are equal with a constant phase difference. It is perhaps more nearly correct to say that the distributors are in "unison." The brushes used on distributors are by no means satisfactory. Copper-wire brushes have been used very extensively. In America a braided-copper brush is employed, while in France a carefully prepared wire brush is used, but neither of these seems to be altogether successful. I think that few of us realized, until we had read this and the previous paper by the author, how vast a contribution Baudot made to telegraph mechanisms. Practically every machine that we have at the moment can be traced back to fundamental designs due to Baudot. The objection to the ordinary reed and phonic-wheel drive lies chiefly in the fact that regulation is individual to each circuit, and I am forced to the conclusion that better results would be obtained by the use of precision apparatus common to all the circuits. This is definitely foreshadowed by the author. I also suggest that, in the method which will ultimately emerge, the rate of the resonant control will be kept constant, i.e. will not be varied to effect phase corrections at intervals under the influence of signals. The use of a Mendonca governor eliminates the reed and its adjustment. This is an excellent feature, since the reed is usually fixed on the wall of the instrument room to avoid effects of vibration, and so is often several feet from the set which it controls. The author states that the pressure of the brushes must be fairly heavy. Some irregularities have been noted in the results obtained, due to variation of the power required on the driving side, and, generally speaking, one doubts whether the method is quite so stable as the reed and phonic-wheel method. As the operating charges form the main part of the cost of a message, the expenditure of a large amount of money is justified if absolute stability of the circuits is secured. Apparatus failure is exceedingly costly and, in my opinion, apparatus stability is one of the most important points which have to be watched. Future progress will probably be made along the lines of distributing alternating current of unvarying frequency to all the circuits. Methods of frequency control were described in the recent paper on the Billingham power station,* but I doubt whether sufficient accuracy will be attained for their use in speed control. The author suggests that the "grid" should provide such current, and I hope that his suggestion may be realized. The infra-acoustic method is particularly interesting, as we have a vast network of telephone circuits to which telegraph channels could be added. Thus we can provide telegraph channels in sufficient number for any purpose.

Mr. J. Davey: Apparently the author is of the opinion that multiplex telegraphy is on the wane, and this certainly seems to be the case, as the present tendency is to introduce teleprinter working. Baudot distributors and retransmitters, however, are still in use at Liverpool Head Post Office. At present we have a line from Dublin to Liverpool, one from Liverpool to Manchester and one from Liverpool to Birmingham. These circuits provide the following type-printing channels, each having a speed of 30 words per minute. One channel from Dublin to Liverpool, one from Liverpool to Dublin, two from Dublin to Manchester, two from Manchester to Dublin, one from Dublin to Birmingham, one from Birmingham to Dublin, three from Liverpool to Birmingham, three from Birmingham to Liverpool, two from Liverpool to Manchester and two from Manchester to Liverpool—18 channels in all. The main distributor at Liverpool sends out correction current to Dublin, Manchester and to the distributor on the Birmingham Baudot at Liverpool. This in turn sends out correction current to Birmingham, and thus these distributors are all held in check by one in Liverpool. The system works well when the lines are free from trouble, and it is one example of what multiplex telegraphy can do. We have a somewhat similar arrangement of circuits between London and Cork, but in this case we are using automatic keyboard perforators with automatic transmitters. Two 2-way channels are being provided between London and Cork, and two each are in existence between Liverpool and London and between Liverpool and Cork.

Mr. A. Munck: The author refers to the difference between telegraphy and telephony; the main difference is, I think, that in telephony the public do the work whilst in telegraphy we do it for them, even as regards the spelling in some cases. The ideal plan is to compromise and make the public do part of the work. This has in part been done by the short-distance typewriter, which has replaced many of our telephone circuits. The most equitable way of charging would be for each customer to pay for the time which he occupies or, in other words, per yard of slip. With regard to errors, the operator has to cope with many difficulties that he should not be charged with, such as bad handwriting, atrocious code words, etc. In spite of this, our periodical examinations show that the average operating errors amount to less than 1 word in 17 000. With regard to the maintenance of cable apparatus, this does not present great difficulty to us, as a previous speaker has pointed out; and at my own station (Liverpool) the time during which the cable has been out of commission due to any plant failure has averaged 1·54 minutes per week during the last 12 months. It is difficult to obtain complete flexibility of the system. We have full flexibility in one direction, as the incoming signals can be forked out and made to serve many cities; Liverpool may share a cable with London or Paris, for instance, in the homeward direction. The difficulty occurs when two stations are required to send into the same cable. This can only be done by letting one fork drive both phonic wheels and then stepping them into phase.

Mr. C. E. Reeve: Telegraphs present quite a different problem from that of an ordinary business proposition which is earning money. The rural telegraph lines, which run through sparsely populated outlying areas where relatively costly plant has to be maintained irrespective of revenue, are often run at a loss—never at a profit. On the other hand, an analysis of the revenue earned by main lines would, I think, disclose a profit. This system is a legacy of a generation other than our own, and, while we may reasonably be expected to find correctives, the responsibility for finding a cure should not be thrust upon the present-day administration. I should like to know what the author visualizes as the design of a machine which would work economically in rural districts. In 1914 a Committee of Inquiry was held with the idea of deciding upon a standard keyboard, but I have not heard of any definite result. Although after reading the author's two papers one would get the idea that we had greatly progressed, I think that we have advanced very slowly. Expenditure on telegraphs might be cut down by providing pure phantom circuits over every telephone cable; the capital and running charges would be extremely small with low voltages in use. Further, the human element seems to be in process of elimination. I believe that the Eastern Telegraph Co. have reduced a large operating staff to what is practically a skeleton maintenance staff, by installing relays mentioned by the author. This is a step on the path of progress, but it is taken at the expense of the craftsman. With regard to the question of brushes, a brush was invented by Halske in 1913 for working the first Siemens-Halske duplex system. This brush was not produced again after the War had broken out and stocks had become exhausted. We could not find out the composition of the metal used in it. It was, I believe, a combination of silver and phosphor-bronze. Whilst it worked on the distributor face, it produced very little attrition. It secured a perfect contact, perfect transmission and apparently eliminated self-inductive discharges when the brush passed from one segment to the other. At the present time we have a good system of teletype, and I should like to know what the author visualizes as the future development of this apparatus. Is the teletype exchange with selective dialling and automatic switching a practical possibility? Would there be need for synchronization of the motor speeds from a universal predetermined centrally controlled rate, or would gang control at the particular office be necessary?

Mr. J. C. Prescott: I should like to ask the author how far it is possible to eliminate phase-swinging in phonic-wheel apparatus, and what is considered to be a reasonable angular deviation due to hunting. I should be glad if he would give me some information as to the methods used for reducing the swing, and as to whether electromagnetic damping is employed to any extent.

---

* See page 1233.

On page 1381 of the paper it is stated that a phonic-wheel motor is polarized from an external source of direct current when it is to be used for operation with alternating currents. What advantage is gained in this way? Polarization is not resorted to in the small phonic-wheel motors used on the Duddell oscillograph; these are operated from the alternating-current supply and they seem to run satisfactorily.

Dr. T. H. Turney: I am particularly interested in the author's description of the methods of overcoming distortion. I had always looked upon signal distortion from Fourier's point of view, that is to say, I regarded it as due to the unequal attenuation and phase shift of the component frequencies in the original signal. It is in the nature of a revelation to me to regard distortion as an unequal attenuation of the differential coefficients of the sent signal. This conception of distortion seems to be similar to that of McLaurin.

Mr. A. J. Pratt (*communicated*): The reference to composited or simultaneous telegraph and telephone working is interesting. Perhaps the author is of opinion that the difficulties mentioned on page 1434, and others of which he is no doubt well aware—with regard to interference to telephone circuits produced by the large telegraph currents—are sufficiently serious to impose practical limitations to the extended commercial use of the composited system of telephone and telegraph working. Simultaneous telephone and telegraph working has always presented some difficulties, and with the introduction of the loaded underground circuit the difficulties have been considerably enhanced. Low-pass and high-pass filters are necessary to block out telegraph frequencies, and, on the other hand, sparking at the relay contacts, for instance, is caused by the use of low-pass filters. Line conditions are varying and unstable and many types of loading coils and degrees of spacing are in use to-day. The interference (mentioned on page 1434) from iron-cored loading coils is not very serious in view of the present-day practice of using loading coils of the dust-core type. Notwithstanding these difficulties with a frequency band for high-grade telephone transmission of 200 to 3 000 cycles per second, the lower range from 0 to 200 cycles should be available for telegraph transmission so long as noise in the telephone circuit can be eliminated. I should like the author to expand his view as to the practical and commercial possibilities of the simultaneous telephone and telegraph system of working, particularly in this country, where the distances between the large industrial and telephone centres are relatively short and easy to negotiate from the point of view of telegraph and telephone cables. There is a further reference to the same subject on page 1450, where the joint use of the telephone network is suggested in order to reduce the cost of the telegram. As suggested in the paper, there would appear to be a greater prospect of success in this direction by reducing the operating costs, by the abolition of retransmission and by putting the burden of the operative work, or a large share of it, upon the shoulders of the user himself, rather than by eliminating a portion of the engineering costs through the introduction of ultra-scientific methods for working telephone and telegraph circuits.

THE AUTHOR'S REPLY TO THE DISCUSSIONS.

Mr. H. H. Harrison (*in reply*):—

London.

Replying to Mr. Herbert, I agree that precision methods of speed and phase control could probably be applied with advantage to inland circuits. This would lead to an increase in transmitting capacity, accompanied at the same time by a greater operating margin at the receiving end. This arises from the fact that, with the abolition of phase-swinging, the importance of shortened receiving segments is considerably reduced. At present only a fraction (about one-half) of a received signal pulse is effective due to the shortened segment. On the receiving face of a 20-segment distributor of the Baudot type each receiving segment occupies an angle of 9 degrees. At 3 revolutions per second of the brush arm the duration of a received pulse is just over 8 milli-seconds. If shortening is abolished, then with 25 segments an additional channel (the duration of a signal pulse is 13 milli-seconds approximately) could be obtained. Actually some shortening would be experienced, since adjacent segments are not in contact with one another, but these figures illustrate the possibilities. It is true that the Mendonca governor is sensitive to load variation and it is really only suitable where the load is very nearly constant, and very light, as it is with a distributor drive. If the public supply is not sufficiently constant with respect to frequency, then gang control in offices with inter-office speed control is the solution of the problem. Correction from the signals themselves is the best method to adopt where very fine divergences are to be obtained, and correction should be effected both ways. To obtain maximum margin, the receiving distributor should be continuously under the control of the master clock which is furnished by the timed signals from the sending end. It is not unreasonable, however, to expect that the a.c. supply of the near future will furnish a simple and direct means of phase and speed control for inland circuits, and the necessity for correction will disappear. The Warren system of frequency control enables public and private time systems to be driven from a.c. mains. The clock mechanisms are driven by a small shaded-pole synchronous motor. The Grünenwald system has been included in the paper because it represents a modern development in a system of machine telegraphy which is still largely used in Europe, South America and the British Dominions. The advantages of the improved form of quadruplex and the morse multiplex reside in the possibility of getting maximum speed out of the line while the channel speed is well within the economic limiting speed of a Morse Code printer. I am not aware of any application of the method described for eliminating duplex "jar." I agree with Mr. Herbert that the telegraph ideal is the possibility of transmission direct from user to user. A very striking example of the economies realized by through switching on a telegraph network is furnished in a paper by Mr. J. A. Webster.* This paper describes the arrangements in use on the Entre Rios and North East Argentine Railways. With the remainder of Mr. Herbert's remarks I am, of course, in thorough agreement.

Mr. Creed refers to the British origin of the Mendonca governor. It was, and is, in use on the Evershed megger, but its real inventor is an American named Duryea, who applied it to the maintenance of constant magneto speed with variable speed of a motor-car engine (see British Patent 26615/1896). Subsequently Lanchester independently invented it, and later Evershed, who did a considerable amount of research work on the best combination of materials for the friction disc and coupling pads, applied it to his well-known megger. It was tried later for train-lighting purposes, but was not a success as, owing to the load to be transmitted, the heat developed between pads and disc became excessive. I do not think that there can be said to be any conflict now between the Morse and 5-unit Codes, nor do I agree that morse will be retained on account of any supposed flexibility. Morse or Wheatstone apparatus, which is ready to work as soon as it is placed on the table, is almost obsolete and the present-day Morse apparatus is a machine telegraph system designed by Mr. Creed himself. Very nearly perfect as this apparatus is, it is not as flexible as the apparatus it replaced, nor can any machine telegraph system be absolutely flexible. Start-stop systems more nearly approach the ideal because their speed is such that they will work over any line from the short local line to the long-distance main line without any readjustment. Morse telegraphy will survive for ship-to-shore radio services where hand-speed operation is in force, because, in many cases, the volume of traffic would not justify the installation of machine telegraphs, while Morse signals can be read with a background of disturbance owing to the selective functions exercised by the human operator. The machine cannot discriminate against any irregularities of this character. Long-distance radio links carrying regular commercial traffic can be and are being operated by machine methods, and morse has no special advantages here. With regard to the substitution of a 6-unit for the 5-unit Code, I am in complete agreement with Mr. Creed. It is interesting to note that Baudot originally used a 6-unit Code in the early stages of the development of his system. Such a code makes it possible to dispense with inversion devices, thus simplifying printer mechanisms, and saves line time on secondary signals controlling the operation of the printer mechanism. So far as the text of a message is concerned, there is no saving of line time, as the inversion signals take the place of the word-spacing signals which would, otherwise, have to be used. The increase of 20 per cent in the length of a letter signal is only of theoretical importance. The difficulty in the way of this change lies in the capital sunk already in 5-unit apparatus by different administrations who would probably be reluctant to move. Telegraphy nowadays has to be considered from the international point of view, and the contemplated change would have to be agreed to by all before it became possible. Mr. Creed has reversed my views on the influence of distance and time on the relative use of telephony and telegraphy. I pointed out that differences of time operate in favour of the telegraph and against the telephone. I agree that, except in special cases, the printed is superior to the spoken word. Especially is this so, as Mr. Creed points out, where difference of language arises.

Lieut-Col. Lee points out that the valve-maintained tuning fork was invented by Eccles and Jordan. I regret that I have given the impression that it was the invention of the Western Electric Co. Sketch (*c*) in Fig. 10 shows one of their methods of controlling a tuning fork driving a phonic-wheel motor, and it should have been stated that this was an application of a well-known method of tuning-fork control. I am glad to have an opportunity of setting this right. The performance data quoted by Colonel Lee form a valuable addition to my paper from the point of view of speed-control possibilities. With accurately controlled forks at two stations, speed differences can become so fine that a difference of phase of 1 degree between the two distributors would require several hours to accumulate. Correction can be entirely dispensed with and phase adjustments made by hand once or twice per day by means of mechanism disclosed in Figs. 53 and 54. Dispensing with the need for correction and, thereby, for correcting mechanism, is only of secondary importance. When constant speed and minute speed difference are simultaneously attained one source of signal distortion is removed and higher speed per channel or, alternatively, more channels may be secured. Where telegraph offices are in different countries some difficulties might at first arise with the control of synchronous motors in each office, but I look to the C.C.I. to formulate standards which would keep matters right. With regard to the Verdan apparatus, it is true that the atmospherics in Table 1 (page 1423), are shown as giving rise to " extras " only, but it is stated that it is found in practice that the majority of disturbances are in this direction and it is a fact that the Verdan system gives good service at times when Morse working has been found impracticable. The figures given by Colonel Lee as to the operating results on " ghost " circuits are most interesting to me as I am sure they will be to other telegraph engineers.

Mr. Wood raises the question of the indefiniteness of the commencement of the regenerated signal owing to the breadth of the " pick-up " segment. Provided that the signalling speed is such that the receiving relay will operate reliably with the breadth assigned to the segments in question, and provided also that there is complete absence of overlap between receiving cycle and retransmitting cycle, the regenerated signals will be true copies of the originals. Where partial overlap takes place, however, distortion can be set up, especially if a run of positive signals is succeeded by a solitary negative pulse. If maximum speed with nearest possible approach to true regeneration is required under these conditions, thermionic valves must be applied between the segments and the first relay in the chain. The only work then for the received signals is to vary the potential of the valve grids, the valves acting as triggers to operate subsequent relays. I agree with Mr. Wood that the arrangement of Fig. 14 is superior to that of Fig. 13. The latter figure was inserted as a record of the inception of the idea of clock control of a vibrating reed. The phase shift of brush B (Fig. 14) is, as Mr. Wood explains, of the utmost importance. The interchangeable gears at each station of a chain of regenerator stations is, as pointed out by him, an important and valuable feature of the Eastern Telegraph Co.'s system. One-way correction on land lines is good enough because of the comparatively low speed of Baudot circuits and the relatively high margin. This is American as well as European experience, but on long and difficult cable circuits 2-way correction is absolutely necessary. I have been experimenting for some time with a system requiring very precise synchronism and have used not only both-way correction but both primary and secondary synchronism on the lines of that discussed in the last paragraph of page 1371. I regret that Higgitt's method of orientation shown in Fig. 113 was not included in the section on speed and phase control, and I agree that it is both ingenious and simple and possesses the same advantages as do those methods shown in Figs. 53, 54 and 58. I am not aware that the duplex "jar" arrangement has been tried. A smoothing inductance in the transmitter lead has been used for many years when superposing a telegraph circuit on a telephone loop, and for precisely the same object as that mentioned by Mr. Wood. I am aware of proposals for unequal channel working but did not know that such were actually in use. The introduction of automatic switching, as described by Mr. Wood, is an interesting example of what I believe will be the trend of telegraph development within the next few years, but, as Mr. Wood says, it is to the inland network that we must look for spectacular economies.

---

* "Intercommunication Telegraph Working," *Proceedings of the Institution of Railway Signal Engineers*, 1929, Part 1.

In answer to Mr. Cruickshank, I mean by the expression "pure wave" a wave in which the electromagnetic and electrostatic energies are equal to each other. The explanation I have given is based on the treatment to be found in Franklin's "Electric Waves," and as the two sets of signals do reach their receivers, under the conditions laid down, the use of the word "interference" is justified whatever the exact transmission process may be. Mr. Cruikshank is correct with respect to Fig. 129(*b*). I overlooked the fact that for the various equations to apply correctly the meshes must be separated from one another by the arrangement of valves shown in Fig. 129(*b*).

In answer to Mr. Kitchen, I have had no experience of running printing telegraph mechanisms with a.c. motors. I should have stated that forks or reeds should be protected from mechanical disturbances. Mr. Kitchen's description of the Cook governor is interesting, and, since the relationship between amplitude and spring tension is secured once and for all at the factory, it represents an improvement in the right direction. The correct adjustment of spring tension by running and observation is a time-wasting process. My remark as to duplex and simplex speeds seems to have been misunderstood. This is no doubt due to my not having stated the case with sufficient definiteness. What is meant by the statement is the following: If S is the *maximum* simplex speed on any given circuit, then, due to inherent out-of-balance quantities in any artificial line formed of a finite number of meshes of capacity and resistance, the combined duplex speed is $1\frac{1}{3}S$. I feel that with the present state of affairs where more lines are available than the traffic requires, multiplex circuits could be given greater stability by using separate lines for up-and-down working and abolishing the extra complication of duplex apparatus and the additional adjustment. I agree, of course, that a duplexed Baudot circuit is superior to a simplexed circuit from the point of view of output, so long as the channel speeds are the same in the two cases. Mr. Kitchen does not describe the method of automatic switching which the Post Office has tried and so I cannot comment on it. I agree that teleprinters should not be placed in small offices where telephone communication to the nearest telegraph office can be economically effected. I cannot see on what grounds Mr. Kitchen bases his very definite statement that machine switching causes excessive delay. First of all, I know of no machine-switching telegraph system in use, and I cannot understand how a properly designed machine telegraph system could give rise to such a condition as he postulates. Machine switching by means of which a circuit can be set up via two or more intermediate switching centres requires, as is known, a few seconds only, and, provided the number of channels (channels which can be obtained from the existing telephone network) are proportioned to the volume of traffic along the route, there should be no delay which would justify the term "excessive." Considerable delay arises at times with the present system of inland telegraphy, and even America provides regional traffic controllers to counteract it [see Bibliography (38)]. I quite agree with Mr. Kitchen that the provision of machine switching cannot be effected without considerable cost, but if inland telegraphy is to be prevented from sinking lower and lower financially, heavy capital expenditure will have to be incurred. The new teletype exchange facilities offered to the public by Mr. Kitchen's department will involve additional cost. The system that will ultimately be developed will certainly require the co-operation of traffic officers, but it is primarily an engineering problem.

Newcastle.

Mr. Baldwin appears to fear that congestion would ensue if machine switching were adopted. I do not think this would arise if the system were designed after a full investigation of the traffic conditions. So far as the number of channels are concerned, it would appear that if dual use is made of the telephone network, more channels would be available than would be required. For example, on the London-Manchester telephone cable some 300 telegraph channels could be formed by merely adding terminal equipment. This would allow, taking an extreme case which would scarcely arise in practice, 300 offices to be simultaneously in connection with Manchester. Terminal equipment would only be added to such channels when actually seized for telegraph traffic. With reference to the speed control of alternating-current motors, if an ordinary synchronous motor is used the speed of this is dependent upon the constancy of the supply frequency. Supply companies are commencing to install systems of frequency control to permit of interconnection, and when this is general an improvement may be expected in the running of small a.c. motors. If an induction type of motor is used, it is possible to control this by introducing a governor which will vary the slip. Of the two causes of trouble with reeds or forks mentioned, the more serious is mechanical vibration. Over a limited range of voltage variation, the change of fork frequency is very slight.

Mr. Wilson's contribution to the discussion is very interesting as it gives us a picture of one branch of machine telegraphy about which very little is known. The craft of the hand-worker is, as Mr. Wilson states, fast vanishing and is being replaced by another craft making much higher demands on the individual.

In reply to Mr. Bramwell, my statement as to the capacity of a circuit when duplexed as compared with its simplex capacity refers to the condition when maximum speed is being sought for. A hand-worked circuit if duplexed certainly has a doubled traffic-carrying capacity, but this may be very much below its maximum capacity and as the speed is raised step by step it will be found that the both-way capacity becomes less than 2 : 1, for reasons which I have given in reply to another speaker. Mr. Bramwell has overlooked the fact that in Fig. 112 the transmitting time does not overlap the receiving time, so that either relay " A " or " B " when about to send out a signal is already on its contact—marking or spacing—" bounce " has subsided and the period of transit time is over. I agree with Mr. Bramwell's final remarks.

The speed of 550 words per minute mentioned by Mr. Bellwood is not a practical one. A Wheatstone transmitter will not work day-by-day continuously at this speed, and at the receiving end the handling of the " slip " would be a stupendous task. As a " stunt " it is all very well, but it is not practical politics. I have seen similar performances when some distinguished visitor has to be impressed, but the transmitter had to be adjusted by skilled mechanics and the adjustments could not be maintained permanently. It is quite true, as Mr. Bellwood points out, that printer speeds are low, but low speeds mean easy maintenance, and, provided the unitary speed is not below skilled typist speed, there seems no reason to attempt anything higher. High-speed printers have been manufactured but they knock themselves to pieces. Optical printers involving photography with developing, fixing and drying processes can operate at extremely high speeds but are complicated and not suitable for employment under conditions to be met with in a telegraph office. Mr. Bellwood asks whether the Post Office method of superposing a telegraph on a telephone loop or superposing a telegraph loop on two telephone loops could be efficiently adopted. I see no reason to doubt this. The sub-audio method only absorbs one telephone pair as against two in Mr. Bellwood's alternative, and as start-stop methods of operation are assumed to be becoming the universal method for inland telegraphs the question of speed does not apply. The word " diplex" must, I think, be taken to mean the transmission of two sets of signals simultaneously in one direction over one wire. The addition of the duplex balance and transmitter and receiver at the other end of the line is necessary where traffic is to be 2-way, but it is conceivable that a newspaper wire, where transmission is all one-way, except for acknowledgments and corrections or other service purposes, would not need these additions. Mr. Bellwood need have no fear as to the possibility of dialling any desired distance. Dial pulses are merely signal pulses and wherever telegraph signals can be sent so also can dial pulses. It does not appear to me to be necessary to load the telegraphs with one-third the cost of any telephone loop used for the dual purposes of telegraphy and telephony. Where such use involves additional equipment which would not be required if the wires were used solely for telephony, the telegraph side would naturally be debited with the cost. The telephone side are entitled to some credit allowance for the use of their line plant, but such charges would surely be such as to encourage the telegraph side of the business. It is impossible to discuss automatic switching adequately without complete traffic data, and I think that the matter must be left there. I cannot see that the switching time over an inland telegraph network should be any greater than in a telephone network such as London. The apparatus will cost a considerable amount, but, as I have stated in answer to another speaker, the telegraphs can only become a healthy, vigorous activity if a considerable capital outlay is incurred.

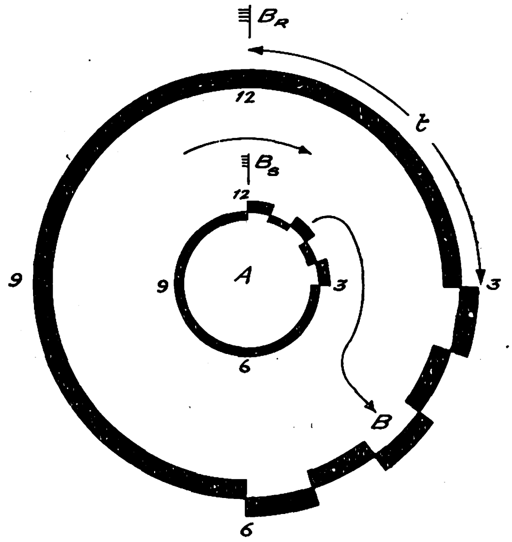

Fig. B.

Liverpool.

Prof. Marchant is right in pointing out that the line of contact between the friction pad and the cone of the Mendonca governor is apt to change slightly, but this has no noticeable effect in practice. Mr. Gill's modification is interesting but it does not seem worth while to complicate the Mendonca governor by introducing it.

Mr. Herbert is in error in stating that there is a difference of phase between the distributors on a machine telegraph circuit. Where line lag exists, it is the *signals* which are out of phase. This is perhaps more clearly seen by reference to Fig. B. Here a quadruple circuit is assumed and the inner circle represents the positive and marking currents sent out from Station A, a letter signal being transmitted on the first quadrant or during the passage over the 12 to 3 o'clock interval. The line lag is assumed to be equal to the time taken to sweep over 90 degrees or one quadrant of the distributor faces. Reception commences at the second station B when the receiving brush B_R reaches the 3 o'clock position, by which time the sending brush B_S will also be at 3 o'clock, having just finished the transmission of the letter signal as reception commences. Thus, except for slight differences of phase due to speed variations, the sending and receiving brushes are always very nearly in phase. I agree with Mr. Herbert's remarks as to the substitution of precision apparatus common to all circuits in place of the present individual regulation. The remarkable results achieved by the Eastern Telegraph Co. confirm this conclusion.

The Mendonca governor ceases to be efficient when the load varies.

I think the alternating-current public supply of the near future will be of a sufficiently satisfactory character to serve groups of a.c. motors in a large telegraph office.

Mr. Davey's remarks illustrate the remarkable flexibility of the multiplex system. With the use of telephone pairs to furnish the channels, interlinking of the character described will be much more simply and efficiently secured, using teleprinters and, where necessary, simple forms of repeater.

Mr. Munck's facts with respect to cable operation are interesting and I agree with him that we should make the public do as much of the work as we can. Large numbers of them do their own telephone operating and I look to the future when they will do their own telegraph operating also.

I agree with Mr. Reeve that we are suffering from the actions of those who have gone before us. Too much was paid for the telegraphs in the first instance, and the concessions granted to bribe the Press of the day to regard with a friendly eye the acquisition of the telegraphs by the State applied a load which should never have been borne. Mr. Reeve asks whether the teletype exchange with selective dialling and automatic switching is a practical possibility. The answer is in the affirmative. Gang control of the motors in a large office would be an advantage and it might be practicable here to provide one motor per instrument table, controlled as to speed, and transmit from this by bevel gears and Bowden wires to four or six teletype machines on the same table, thus saving individual motors.

In answer to Mr. Prescott, various types of viscous damper are applied to phonic-wheel motors to reduce phase-swing, and such dampers usually take the form of a hollow flywheel loaded with mercury. The eddy-current brake has also been employed. It depends entirely upon the form of motor and arrangement of pole-pieces as to whether polarization is necessary. The motor in Fig. 17 would not run without the polarizing windings.

In reply to Mr. Pratt, the short distances prevailing in this country negative the value of dual use of telephone pairs, but as the multiplex is replaced by start-stop apparatus, and if and when machine switching is introduced, the necessary multiplication of telegraph channels will put another complexion on the matter.

THE TWENTY-FIRST KELVIN LECTURE.

"SOME RECENT ADVANCES IN THE ELECTRON THEORY OF METALS."

By R. H. Fowler, F.R.S.

(*Lecture delivered before* The Institution 1*st May, and before the* Scottish Centre 16*th May*, 1930.)

(1) Introduction.

In acknowledging the great honour you have done me in asking me to deliver the Twenty-First Kelvin Lecture, I must offer some preliminary words of explanation and apology. No apology is needed for speaking to you on the electric and magnetic properties of metals. I imagine nothing could be more appropriate or more in sympathy with the interests of that great pioneer whose memory this Lecture annually perpetuates. Nor, I take it, is any apology needed for speaking about abstract theory, as yet of little or no practical importance. We can all agree with the President of the Royal Society in his last anniversary address, that it is by the reciprocal interactions of theory and practice or experiment that knowledge and power advance. This point need not be laboured here. But I do feel rather apologetic for inflicting on you, after so short an interval, the new quantum mechanics or wave mechanics—these are merely two names for the same thing, though apparently not everyone is yet aware of this identity. But my best excuse (and an amply sufficient one) is that quantum mechanics has come to stay and that no real progress in the theory of metals (or, for the matter of that, of other forms of matter) is possible without it.

I shall be concerned in this Lecture with particular applications and results of quantum mechanics rather than with first principles. But still I cannot avoid some attempts to give a simple physical meaning to some parts of the general theory. This is a difficult task at the present time. For the situation is that within a quite definite field, equivalent to non-relativistic particle mechanics, quantum mechanics is, I am confident, in its final form, though its ideas are still so novel that we do not often (if ever) talk about them intelligibly. We may still need a new Einstein to make our theorems more perfectly relativistic; we certainly need a new Lagrange to deepen our powers over complicated problems. But these are details compared with the appalling fact that we have already at our disposal "Newtonian" quantum mechanics which we can use with complete confidence, yet hardly ever talk about in a satisfactory physical way.

My object is to give you now a rough survey of the electron theory of metals—good solid conductors of electricity—as it stands at present. I most emphatically do not guarantee that what I say is up to date on every point, but if I can convey to you the standing of the theory, as re-established by quantum mechanics, I shall be more than satisfied.

(2) The Nature of a Metal and Classical Theory.

I suppose that the electron theory of metals effectively began with Drude. At any rate the triumphant explanation by his theory of the relationship between electrical and thermal conductivities gave it its first real start. The theory, of course, was based, and is still based, on the simplifying approximation, now fairly well justified, that a metal consists of a number of positive ions—atoms that have lost one or more electrons—more or less permanently resident at the positions required by the lattice structure of the metal crystal, together with the lost electrons free to move about among the ions. The simplest assumption of all, which should be correct for monovalent metals like the noble metals and the alkalis, is that each atom sets loose exactly one electron. The electrons and ions act on one another with the usual Coulomb forces, but to the first approximation the effect of these from the point of view of an electron is to make the interior of the metal an electrically neutral region of roughly constant *positive* potential, such that work must be done to extract an electron and leave it at rest outside in free space at zero potential. Inside the metal, then, to this approximation the free electrons will behave like a perfect gas of uncharged partilesc of mass m, the mass of the electron. In the next approximation we must recognize that there are regularly arranged spots (the ions) where there is a more or less violent deviation from uniformity; classically a moving electron will suffer collisions at these spots. The electrical resistance of a metal is determined by the rate at which these collisions dissipate the directed momentum in a beam of moving electrons. The mean space rate of dissipation of this momentum, p, involves a length which one calls the mean free path, λ,

$$\frac{dp}{dx} = -\frac{p}{\lambda}$$

The classical theory included in its initial successes even the prediction of conductivities of the right order for not unreasonable values of λ. But it was ruled out of court by at least one outstanding difficulty, that a perfect gas of one free electron per atom would necessarily contribute $\frac{3}{2}R$ to the specific heat of the metal, that is, 3 calories per gramme-atom per degree Kelvin, whereas no comparable contribution is allowable. The vibrations of the massive ions satisfactorily account for the whole, and there were other related difficulties. The main difficulties could have been turned by supposing that there were only a few free electrons doing all the work; they would then require to have correspondingly long free paths. The surprising effect of small traces of impurity upon conductivity requires these long free paths to be real. But classically it was quite impossible that the free path should be much longer than the atomic spacing in the lattice.

(3) The Quantum Mechanical Revision.

All these and similar difficulties have been entirely removed by the quantum mechanics working on Drude's model of a metal quite unaltered. In fact, it was the dynamics of electrons, not the physical model of a metal, which was wrong and impeding progress. A recognition of some of the more subtle features of quantum mechanics is required to put us on the right track. Let us now approach the problem of metals afresh, starting with the quantum mechanical behaviour of a single electron in the approximate potential field provided by our model of a metal. Quantum mechanics assigns to any such system a certain number of possible stationary states whose energies are fixed by the condition that solutions of a certain linear differential equation (Schrödinger's) shall exist, satisfying certain obvious physical requirements. If V is the potential energy of an electron, h Planck's constant, and ∇^2 the familiar operator of Laplace, then this equation is

$$-\frac{h^2}{8\pi^2 m}\nabla^2\psi + (V - W)\psi = 0$$

and the possible values of W are the possible *total* energies of the electron. Now our picture requires that V shall vary rapidly near the metal boundary, and otherwise be either 0 or $-C$, according to whether we are outside or inside. The transitional region in Fig. 1 is probably fairly thin, but we need not at this stage worry about it, for it can be shown that it makes no difference if we take it instead as a sudden step. Again as this step is fairly high (10 volts or so would be high for present purposes) it makes little difference if we take it infinite. We have then to solve the wave equation

$$-\frac{h^2}{8\pi^2 m}\nabla^2\psi - E\psi = 0$$

where E is *kinetic* energy, subject to the condition that $\psi = 0$ on the boundary and outside, where V becomes infinite.*

It is easy to solve this equation if the region within which the electrons are confined is a rectangular box, of edges a, b, c. The shape of the box can be shown not to matter for practical applications. For this simple shape the possible kinetic energies are given by

$$E = \frac{h^2}{8m}\left(\frac{r^2}{a^2} + \frac{s^2}{b^2} + \frac{t^2}{c^2}\right)$$

where r, s, t are positive integers and the corresponding function ψ is

$$\psi = \sin\frac{\pi r x}{a}\sin\frac{\pi s y}{b}\sin\frac{\pi t z}{c}$$

We now find, on account of the smallness of h and in spite of the smallness of m, that if we take a box of any ordinarily small size, let us say 1 mm^3 or even a cube of edge $\frac{1}{2} \times 10^{-4}$ cm, a wavelength of visible light, the energies of the possible stationary states lie so close together that we cannot distinguish them for practical purposes from the continuous distribution allowed by classical mechanics. If we then packed into such a box a number of electrons comparable with the number of atoms in the same volume of metal, *and if they did not interfere with one another in any way*, we should get a distribution of free electrons indistinguishable from the classical (Maxwellian) distribution of Drude's theory—with the same properties and the same failure as a representation of an actual metal. But here quantum mechanics makes its first really fundamental contribution in this field, as was first pointed out *for metal theory* by Sommerfeld. It is that one can never, even in zero-order approximation, as it were—even in the limit of vanishingly small interactions of the particles' mutual potential energy—treat a composite assembly of two or more electrons by simple combinations of the states possible to one electron. To the present depth of our analysis, at least, this is not because of the Coulomb repulsion between the electrons. It applies equally in the limit when this may be supposed to be neutralized. It is not because of other forces which might be regarded as giving the electron *a size*. It is something far more fundamental, entering into the quantum dynamics because its equations are all *linear* in the fundamental wave-function ψ, and entirely foreign to classical particle dynamics because its equations are essentially non-linear, for example in the momenta. It is mathematically like a species of interference due to the superposition of wave systems, with which you will all be familiar in ordinary oscillating systems, though this analogy must be used with extreme caution. One is apt to think of the de Broglie wave systems associated with particles by the quantum mechanics as wave systems like electromagnetic waves in the ordinary space-time of physics. But the wave system of a pair of electrons, for example, is, so far as it is anything describable, strictly a wave system in a six-dimensional space, and so on for more electrons. Electromagnetic or optical analogies are invaluable, but when we wish to use our results by interpreting them in physical space-time, the greatest caution may be necessary. Well, whatever may be the correct physical description, the theory is certainly of such a form that possible states of two or more electrons present in a single box together are confined to a selection only of all the states that can be built up by repetition from the states of a single electron. The proper selection can be simply described by saying that *no two electrons can ever be simultaneously in the same stationary state*—a saying which holds for all assemblies

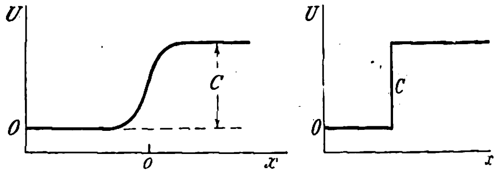

Fig. 1.

---

* This is the form to which our physical requirements reduce in such a limiting case.

of electrons, e.g. for a single free atom, for which it was first detected semi-empirically by Pauli, being generally now known as *Pauli's principle*. The principle must be strictly interpreted. We shall have to admit later on that electrons have a spin of their own and an associated magnetic moment which is capable of exactly two orientations, along and against any magnetic field. These two orientations may be regarded as the two possible values of another quantum number which, with r, s and t, makes up four for each electron. The strict enunciation of Pauli's principle is, then, that in any assembly of electrons no two electrons may ever have the same *four* quantum numbers.

I have deliberately stressed the independence of Pauli's principle of any crude mutual potential energy between the electrons. This is the correct and only not-misleading attitude to adopt at the present development of the theory. But perhaps if the recent researches of Eddington [*] prove ultimately fruitful one may hope to fuse together Pauli's principle and Coulomb interactions as two manifestations of a single, more comprehensive, scheme.

As I have said, Pauli's principle is a direct consequence [†] of the laws of quantum mechanics, and it was its introduction into metal theory by Sommerfeld that gave metal theory its new start. Allowing for Pauli's principle, we find that the number of free electrons with kinetic energies between E and $E + dE$ in a unit volume of an idealized metal, instead of being given by the familiar distribution law of Maxwell

$$n(E)dE = A'e^{-E/kT}E^{\frac{1}{2}}\,dE \quad . \quad . \quad . \quad (1)$$

is given by the slightly different law of Fermi and Dirac

$$n(E)dE = \frac{4\pi(2m)^{\frac{3}{2}}}{h^2} \cdot \frac{E^{\frac{1}{2}}\,dE}{1 + e^{E/kT}/A} \quad . \quad . \quad (2)$$

A, A' are constants so adjusted that the total number of electrons of all energies is correct—say, the equivalent of one per atom for a monovalent metal. It will be noticed that equation (2) reduces to equation (1) when A is very small, but there is no resemblance when A is large. When A is large its value is given approximately by

$$A = e^{\bar{E}/kT}, \quad \bar{E} = \frac{h^2}{8m}\left(\frac{3n}{\pi}\right)^{\frac{2}{3}}$$

where n is the total density of the electrons.

Just here is where the very small mass of the electron takes effect. Obviously A depends on the mass, and turns out to be large for electron densities of the order of metallic ones, so large, in fact, that the distribution would be quite unclassical even, for example, for copper at 1 500° K. This is shown clearly by the actual distribution law sketched by Nordheim in Fig. 2. At ordinary room temperatures, and even well above, the distribution is such that, nearly enough,

$$n(E) \propto E^{\frac{1}{2}} \qquad [\bar{E} < \bar{E}]$$

$$n(E) \propto e^{-E/kT}E^{\frac{1}{2}} \qquad [\bar{E} > \bar{E}]$$

What happens is that at all such temperatures practically every possible electronic state for which $E < \bar{E}$ is occupied by its one electron, while for $E > \bar{E}$ practically all are empty. The very few electrons that are there are too few to worry each other, so that they can obey Maxwell's law.

We find at once that the specific heat difficulty melts away. One can see at a glance from Nordheim's figure that the change of energy content with change of temperature must be very small. Detailed calculation confirms this and gives the total kinetic energy, $E_{kin.}$,

$$E_{kin.} = \frac{\pi}{40} \cdot \frac{h^2}{m}\left(\frac{3n}{\pi}\right)^{\frac{5}{3}} + \frac{2\pi^3 mk^2T^2}{3h^2}\left(\frac{3n}{\pi}\right)^{\frac{1}{3}}$$

from which the specific heat contribution is utterly negligible. (It is in fact *too* small, and later more refined calculations by Bloch [*] make it rather larger generally and possibly much larger in a limited region, so that it is able to account in a most satisfactory way for certain interesting specific heat anomalies such as are found, for example, by Simon [†] at fairly low temperatures for grey tin and other metals.) The constant term, on the other hand, is large; the electrons have a large "zero point energy." But this is without importance for metallic phenomena.

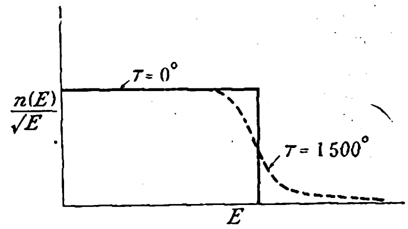

Fig. 2.

(4) The New Conduction Theory.

So far, so good—now comes the real crux. What happens in conduction problems, which are not equilibrium states but states of steady flow?

In a preliminary survey Sommerfeld revised Lorentz's calculations by using the new equilibrium $n(E)$ instead of Maxwell's, and showed that to give observed conductivities the mean free paths must be very long. This is all to the good, as we have seen for empirical reasons, but classically a free path in a metal of from 10 to 100 interatomic distances seems to be nonsense. Quantum mechanically, however, it is just what we must expect, as the work of Houston,[‡] Bloch [§] and Peierls [||] has shown us. For if one examines the behaviour of an electron now no longer in a region of uniform potential but in a potential with variations which are perfectly space-periodic, one finds that though these periodic variations alter the energies of the stationary states of an electron in our box yet they do not affect at all its power to move freely through the box in a given direction. Such perfectly periodic variations of potential can correspond only to a metal which is a perfectly pure, perfect single crystal at zero temperature, assuming that then all the ions are at rest relative to each other. But in such a substance the mean free path of an electron with a kinetic energy of a few volts should be infinitely long, and the substance should possess an infinite conductivity. One can give an analogy to these long or infinite free paths from physical optics. Light in passing through an optically homogeneous medium such as air or many crystals is to a first approximation not scattered or absorbed at all, though every molecule is a potential scattering centre. As was first shown by the late Lord Rayleigh, it is only local deviations from perfect uniformity that scatter the light; deviations which in a dust-free gas are probably fluctuations of concentration and in a crystal flaws and foreign bodies. Just so the de Broglie waves of the electron are not scattered by perfectly regular lattices but only by random deviations from perfect regularity, due to thermal agitation, to strains or to impurities.

---

[*] *Proceedings of the Royal Society*, A, 1930, vol. 126, p. 696.

[†] This is not an entirely correct statement. Quantum mechanics cannot yet predict that electrons will in fact obey Pauli's principle; it can as yet only show that if initially all electrons obey this principle, they will continue to do so for ever.

[*] *Zeitschrift für Physik*, 1928–29, vol. 52, p. 555.

[†] *Berliner Berichte*, 1926, p. 477.

[‡] *Zeitschrift für Physik*, 1928, vol. 48, p. 449.

[§] *Loc. cit.*

[||] *Annalen der Physik*, 1929, vol. 3, p. 1055; and 1930, vol. 4, p. 121

This description, however, is still not entirely adequate. It is quite certain, both theoretically and from X-ray evidence, that at the absolute zero of temperature the ions of a metal crystal are not at rest in their positions of equilibrium but oscillating about them, the whole crystal containing a considerable irreducible zero point energy of oscillation. This fact, which at first sight appears destructive of the theory, urges a closer investigation, for conductivities certainly tend to infinity in favourable cases as the temperature tends to zero, even apart from questions of supra-conductivity. It is then found that one cannot properly discuss the mean free path without investigating in detail the exchange both of energy and momentum between an electron and the lattice, which must occur when a free path is terminated. One can analyse the motion of the ions in the lattice into elastic waves in the manner of Debye in his theory of specific heats. In order that a free path may be terminated it is necessary:—

(1) That an electron of energy E and momentum p shall be transferred to E', p', *which latter, by Pauli's principle, must be a vacant stationary state.*

(2) That the oscillatory state of the lattice shall change to a new state absorbing the energy and momentum differences $E - E'$, $p - p'$.

At high temperatures there is comparatively little difficulty in fulfilling these requirements, but at low temperatures Pauli's principle makes it difficult for an electron to do anything but gain energy, while the oscillations of the lattice, being almost entirely in their lowest state, find it almost impossible to lose energy. Thus the chance of exchanges (in spite of zero point energy), and with that the resistance, rapidly diminishes.

Quantitative investigation on these lines has been carried through exactly for high temperatures and yields an electrical resistance varying as T, in admirable agreement with experiment. At low temperatures the investigation is much more difficult, and theoretical resistances varying like T^3, T^4 or T^5 have been obtained. While any of these is, generally speaking, in fair agreement with experiment, it seems to me that the final investigation has yet to be made. We may, however, rest well content with what has been done until the next step can be taken in relating the theory to supraconductivity. This step has not yet been taken. It may be connected with the theory of magnetic effects, about which I shall say something later in connection with Kapitza's experiments.

(5) THERMO-ELECTRIC EFFECTS.

Before leaving the subject of conductivity I should record that the theory as so far developed gives an explanation of reversible thermo-electric phenomena, which in a general way is entirely satisfactory. The various thermodynamic relationships are of course preserved, and the Thomson and Peltier coefficients are given, even by Sommerfeld's version, values of the right general order of magnitude and type of variation with absolute temperature. The refinements introduced by Bloch and Peierls could no doubt be made to give a very satisfactory account for many metals. I should like to mention in conclusion a valuable critical article on these effects and their relationship to equilibrium states recently published by Stern.*

(6) EMISSION OF ELECTRONS.

We have so far tacitly assumed that all the electrons stay for ever in the metal, as of course they would have to do if the potential step at the surface were infinitely high. But if the step is finite no part of what precedes is effectively altered, except that formula (2) indicates that there are present in the metal at any time a certain number of electrons (depending on the temperature) with sufficient energy to escape. Since free paths are rather long, it is sufficient to ignore the periodic lattice structure in the potential and consider what happens when an electron of kinetic energy E falls on a potential step or hill, in which to a first approximation the potential is a function of the distance from the boundary alone. It is easy to show that in such a problem the motion of the electron parallel to the surface is unaffected, and the problem resolves itself into a one-dimensional one. We can now confine attention to a stream of electrons of energy W in its motion normal to the surface incident from inside the metal on potential hills of various shapes. Typical natural and idealized boundary hills are shown in Fig. 3.

Now the classical solution of this problem is rather hard-and-fast and gives no scope for the observed variety. The electron would then always come out if $W > B$, the summit height of the hill, and never if $W < B$. In the quantum mechanics, however, things are very different. The electron never comes out if $W < C$, the *final* height of the step, but always has a non-zero chance of coming out if $W > C$, even though $W < B$. If we call this chance of emergence $D(W)$ and $N(W)dW$ the number of electrons incident on unit area in unit time with normal energies between W and $(W + dW)$, the total saturated current I per unit area which the metal can emit (supposing it is all collected as in the usual thermionic measurements) is given by

$$I = e\int_0^\infty N(W)D(W)dW$$

---

* *Proceedings of the Royal Society*, A, 1930, vol. 126, p. 570.

Now on Sommerfeld's theory we know $N(W)$, and this theory is amply accurate for the present application. We can calculate $D(W)$ and hence the thermionic current I. I think one may say that these calculations are successful, for they show that $D(W)$ is sensitive to the nature of the hill, *that is to the nature of the surface layer, which may often be a layer of impurity present by accident or design.* The theoretical current is given by the formula

$$I = AT^2e^{-\chi/kT}$$

where A and χ are constants characteristic of the emitter. This is of the well-known proper empirical form, but the theory further accounts correctly for the empirical correlation between A and χ (the work-function), by means of the effect of these potential hills. I do not want to spend more time on these points now. I dealt with them in detail in the Boyle lecture at Oxford this time last year. I think it is fair to say that, using perfectly natural assumptions as to the nature of the boundary hill, the usual phenomena of emission of electrons from hot metals, under very strong electric fields and under the influence of light, can to a first approximation be accounted for to our complete satisfaction. I think, however, it would interest you if I said a word or two more about how it is that an electron can go through a region in which its kinetic energy is apparently negative. Its chance of going through is large if the region is very thin, and dies away exponentially as the region widens. When we consider the wave nature of the electron, regarding it as a train of de Broglie waves, we see that this is closely analogous to a well-known phenomenon of physical optics. If light is incident on a plane interface at an angle greater than the critical angle, there is total internal reflection. But if the second medium is very thin, only a few wavelengths thick, and followed by a third medium the same as the first, there *is* a weak transmitted beam formed in the third medium after all.

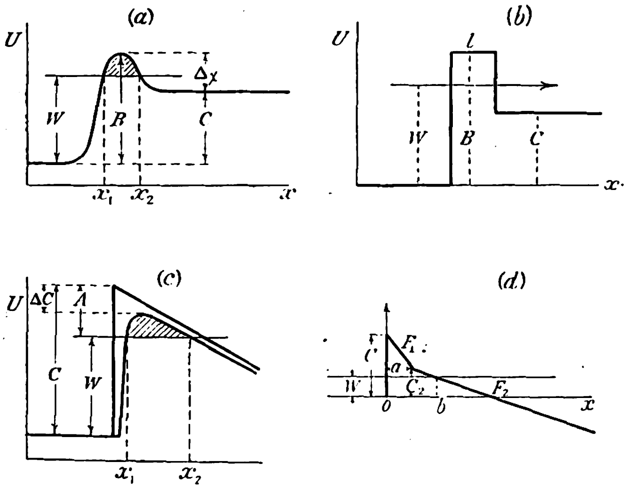

FIG. 3.—Typical natural and idealized boundary potential hills.

(*a*) A natural type of hill when an electro-positive mono-molecular layer is present and the image force is ignored; (*b*) The same, idealized for simplicity of calculation, but without loss of any essential feature; (*c*) An idealized hill (a precipice) with a strong external field of force helping to pull out the electrons, and the same hill modified by the image effect. (This modified type of hill explains the Schottky effect, and the unmodified the ordinary auto-electronic discharge); (*d*) A hill with two slopes, one intrinsic and the other that of the applied external field, explaining the combined effect of strong fields and mono-molecular surface layers.

(7) MAGNETISM AND FERROMAGNETISM.

We have been able to advance so far ignoring the specific interaction of the Coulomb forces between each pair of electrons or ions. But Heisenberg * has shown that when these are taken into account, and also the magnetic moments of the electrons themselves, the theory, though still in a larval stage, gives a beautiful account of ferromagnetic phenomena.

The first step in this part of the theory was really due to Pauli † and concerns the approximation in which we still neglect the Coulomb interactions. We infer from atomic spectra that every electron has a spin or moment of momentum of $h/(4\pi)$, that is, a one-half quantum according to ideas with which we have been familiarized long since by Bohr, and at the same time a magnetic moment of one Bohr magneton. The Bohr magneton is the magnetic moment of any electronic orbit in any atom in which the electron has just one unit, $h/(2\pi)$, of orbital angular momentum. Thus the ratio of magnetic moment to angular momentum for the intrinsic spin of the electron must be just double the ratio of these quantities for any electronic central orbit. (Incidentally, this fits beautifully into the later versions of relativistic quantum mechanics which we owe to Dirac.) If, then, our free metallic electrons carry each a Bohr magneton the axis of which can be turned along and against any imposed magnetic field, why are the alkalis and noble metals not strongly paramagnetic with a temperature-dependence similar to that of the classical gas-theory of Langevin? The answer is that once again Pauli's principle intervenes to prevent the accumulation of the electrons at any reasonable temperature into states in which an appreciable excess are orientated along the field. The susceptibility of our electron gas is not difficult to work out exactly, though I shall not attempt to do so here. It turns out that there is theoretically a slight residual temperature-independent paramagnetic susceptibility of the same order as the usual diamagnetic one, which, in combination with a normal diamagnetic effect from the ions, accounts very satisfactorily for such paramagnetic effects as are actually observed in the lighter alkalis. These effects are really extremely small, and from here on we shall ignore them and speak as if our idealized metals, neglecting specific interaction effects, are (as they should be) magnetically neutral. We have, of course, assumed here that the ions are inert, as they would be for the monovalent ions of the alkalis and the noble metals, which contain only completed groups of electrons.

In introducing his theory of ferromagnetism, Heisenberg points out that as a *formal* explanation of the whole body of ferromagnetic phenomena, Weiss's familiar theory is completely satisfactory. The essence of the theory is that there must be in the total internal energy of a ferromagnetic substance a rather large term which depends in a certain way on the magnetization. Granted the existence of this term, known as Weiss's molecular field, everything fits together as it should, but the difficulty has been to account rationally for its existence, since the actual magnetic energies involved are some 10 000 times too small. This defect quantum mechanics and Heisenberg have now removed.

---

* *Zeitschrift für Physik*, 1928, vol. 49, p. 619.

† *Zeitschrift für Physik*, 1927, vol. 41, p. 81.

Heisenberg starts by directing attention to the *gyromagnetic anomaly*. You know that there is an effect, sometimes called the Richardson-Einstein-de Haas effect, in which when a bar of metal is magnetized it acquires simultaneously a proportional angular moment of momentum which can be actually measured if the suspension is sufficiently delicate. Since all atomic orbits of electrons have one constant ratio, $e/(2mc)$, for magnetic moment to mechanical moment of momentum,[*] one expects to observe a constant ratio between the magnetization and the angular momentum generated, from which e/m may be calculated. The constant ratio is found, but for all ferromagnetics, for which alone until quite recently experiments have been made, the value of e/m so observed has exactly twice its expected value. This is the so-called anomaly, but the observed value is exactly what one would expect if the magnetization were contributed entirely by the orientation of the intrinsic spins of electrons and not of their orbits at all. We assume, therefore, that the magnetism of a ferromagnetic is derived entirely from the orientation of the spins of its loosely bound or free electrons. Is it then possible to account for the energy of Weiss's molecular field by any obvious terms which we have hitherto disregarded in our simple metal theory?

Heisenberg's affirmative answer is delightfully simple. It is that the necessary terms are to be found in the effect of the Coulomb forces—the electrostatic repulsions and attractions—which must now be taken into account. In this step, however, we meet one of the most elegant subtleties of quantum mechanics, which I will try to explain by using the simplest possible example.

In order to get a feasible method of approach to the interaction problem, Heisenberg idealizes the metal in a different way from that which we have used hitherto. He imagines the crystal lattice to be composed of *atoms*, not ions, and expanded by continuous growth of the lattice constant until all the atoms are rather far apart. This looks so different a model as almost (if accepted) to deny the validity of our old one—but this inconsistency is only superficial, and it has in fact been shown by Bloch [†] (at least, I think his argument is valid) that one can get similar effects to Heisenberg's by putting the interactions into our original model; the necessary technique is, however, more complicated and we may follow Heisenberg, recognizing that there is nothing inconsistent with our previous model in his method of approximation, even if the magnetic and conduction electrons are the same, as recent experiments seem to establish. We must therefore discuss the possible stationary states and energies of a large number of regularly arranged similar atomic systems each containing one, two or a few electrons in similar orbits sufficiently loose for the interactions to matter. The large number, though essential to represent a metal, introduces merely complications of detail but none of kind: we can confine attention to *two*, and for purposes of illustration to two hydrogen atoms in their normal states.

Now here again the linearity of the wave functions comes in. It is impossible, when account is taken of the electrostatic interactions, for there to be a stationary state in which one electron is in one atom and the other in the other. If we could start with a particular assignment we should still find after a time, depending on the distance apart, that the electrons had changed places. When the atoms are fairly close together these exchanges become quite rapid and the corresponding energy term—the electrostatic interchange energy, as it is sometimes called—quite large and nearly comparable with the unperturbed energies. The system, of course, has actual stationary states (in fact two) of definite energies, which may be regarded as built up by superposition in definite ways out of the unperturbed solutions with the electrons in their separate atoms. The two states have quite different energies which vary differently with the distance apart of the atoms. In one of them the electron-spins and magnets balance each other out and the system has no magnetic moment. In the other the spins have to be parallel and the system has a magnetic moment of two Bohr magnetons. The energy difference of the two states, due to the electrostatic interchange term, is of altogether greater order, at least when the atoms are fairly close together, than the magnetic energy terms themselves. Now suppose we consider a number of such pairs set parallel, and far apart from each other in a magnetic field. The magnetic field will alter the distribution of all the electron magnets (to what exact amount, of course, it is part of Heisenberg's problem to calculate) and therefore the relative number of pairs which are neutralized or possess a magnetic moment, and of course the orientation of the latter. It will therefore have to alter the distribution of the pairs among their two stationary states, and therewith the energy content of the whole system, and that, too, by an amount depending on the magnetization, which is very large compared with the magnetic energies themselves. Here is the true origin of Weiss's molecular field! The atoms in a real metal lattice, each with an electron in a similar orbit, present a problem exactly similar in type, though it requires the help of abstract group theory conveniently to carry through the calculations. We can now safely proceed to the result of these calculations. Heisenberg finds, for a metal in which there is one "active" electron per atom, that in the equilibrium state the magnetization σ is given by a root of the following equations:—

$$\frac{\sigma}{\sigma_0} = \tanh x \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$2x = \frac{e}{mc} \cdot \frac{h}{2\pi} \cdot \frac{H}{kT} + \frac{\sigma}{\sigma_0}\left(\frac{zJ_0}{kT}\right)\left(1 - \frac{J_0}{kT}\right) + \frac{zJ_0^2}{2k^2T^2}\left(\frac{\sigma}{\sigma_0}\right)^3 \quad (4)$$

These equations are essentially the same as Weiss's. In them σ_0 is the maximum possible magnetization, σ the equilibrium magnetization at temperature T under a magnetic field H, k is the gas constant for one atom, z is the number of nearest neighbours to any given atom in the metal (Heisenberg neglects all interactions except between nearest neighbours), and J_0 is practically the interaction energy which gives the energy separation between the stationary states of a pair of neighbours. In order that the metal may be capable of ferromagnetism J_0 must be *positive*; in order that the Curie point may be at a reasonably high temperature J_0 must be rather large. Heisenberg can show in a general way that these conditions are rather difficult of fulfilment and that ferromagnetics might be expected to be rare and to be found only (as they are) among the metals of least atomic volume—a genuine triumph! *

---

[*] Here c is the velocity of light, and e/m the ratio of charge to mass for the electron.

[†] *Zeitschrift für Physik*, 1929, vol. 57, p. 545.

(8) KAPITZA'S EXPERIMENTS ON CONDUCTIVITY IN STRONG MAGNETIC FIELDS.

We have now glanced cursorily over that part of the field in which quantum mechanics has consolidated the position of the theory, ignoring, for lack of time and space, many pretty corners. I would now direct your attention to most interesting results recently obtained by Kapitza, not yet accounted for by quantum mechanics but promising to throw much light on the theory of metals. It had been believed, on the evidence previously available, that the resistance of a metal was increased by a magnetic field H by an amount proportional to H^2. Kapitza has shown that for larger fields this is not true, but that the actual change of resistance can be very closely represented by a formula of the following type:—

$$\frac{\Delta R}{R} = \beta\frac{H^2}{3H_k} \qquad [H \leqslant H_k]$$

$$\frac{\Delta R}{R} = \beta\left(H - H_k + \frac{H_k^2}{3H}\right) \qquad [H \geqslant H_k]$$

This form has been confirmed by later experiments by Meissner. ΔR and H_k appear to be independent of the temperature for a given specimen, but H_k is violently sensitive to the mechanical treatment to which the specimen has been subjected, and also to its purity. Naturally this is not the only formula which would represent the facts, but it does represent them in what appears to be a significant way, and we shall accept it provisionally here. The form suggests that there are random disturbances in the metal which have the same effect as, and combine vectorially with the effect of, an externally applied magnetic field, and that the effect on the resistance of this composite magnetic field is directly proportional to its strength H and not to H^2. The above formulæ are derived on this hypothesis from the combined effect of an external field H and an internal field H_k, the latter averaged over all directions. It must be confessed that a large primary effect on the resistance proportional to $|H|$ is at present most surprising theoretically, but theory is not yet in a position to deny the possibility and the deductions from this interpretation are too interesting to be ignored. We are required and enabled by this theory to analyse the ordinary resistance of a metal into two parts—an ideal resistance R_i and an additional resistance ΔR_0 due to the H_k. The former depends only or mainly on the temperature and must be the resistance which we have been theoretically studying hitherto. The additional ΔR_0 is approximately temperature-independent, but depends on the mechanical state and treatment of the specimen and its content of impurities. Moreover, ΔR_0 as obtained in this way should be such that it is the same as the residual resistance observed by Kamerlingh Onnes at very low temperatures. This correlation appears to hold in fact. R_0 should also, when deducted from the actual resistance, leave behind an R_i the same for all specimens of a given metal. This also it appears to do. The hypothesis suggests, further, that perhaps the onset of supra-conductivity is concerned with the sudden disappearance of ΔR_0 rather than of R_i, and that perhaps R_i, if one could measure it properly, ultimately tends violently to zero, perhaps like $e^{-b/T}$. All this is still very speculative but should encourage further advances both in theory and experiment.

(9) CONCLUSION.

It must not be thought that I am too optimistic about the present position of the theory of metals. There is much still to be done. I am optimistic to this extent—that I think that quantum mechanics, as at our disposal to-day, is entirely adequate for a final electron theory of metals, or for any other physical theory which can treat the velocity of light as infinite. But metal theory is still far from adequate; we have still to select the proper model and still more to show that it *is* the proper model. By that I mean, of course, that part of the complete theory of metals is to deduce from the properties of atoms and the principles of quantum mechanics that a collection of, say, copper atoms with a reasonable energy content will form a metal and not, for example, a gas. Further, having formed the metal, the theory must specify what simplications may or may not be made in the further treatment of conduction. In the work I have described these more fundamental problems have not been touched, but I think that a very promising beginning has been made on them by Slater.* It appears likely that this work and the complete theory when it comes will very greatly modify the simple model which we have used hitherto. But part of my faith in quantum mechanics is derived from the fact that, give it any physically reasonable model, it provides results which are always in good sensible accord with the requirements of experience. Experimenters and theoreticians alike, we can all, I think, press forward with our work in the confident expectation that we are on the right lines and that progress will be sure and not particularly slow.

---

* BLOCH (*Zeitschrift für Physik*, 1930, vol. 61, p. 206) has still further advanced the theory by improving it for low temperatures with the help of very important new methods developed by SLATER (*Physical Review*, March 1930).

SURGE INVESTIGATIONS ON OVERHEAD LINES AND CABLE SYSTEMS.

By S. W. Melsom, Member, A. N. Arman, B.Sc., Associate Member, and W. Bibby, B.Sc., Associate Member.

[*Paper first received* 17*th December*, 1929, *and in final form* 20*th February*, 1930; *read before* The Institution 10*th April*, *and before the* West Wales (Swansea) Sub-Centre 25*th April*, 1930.]

Summary.

The paper describes measurements of surge voltages made under actual working conditions on 33-kV transmission lines both overhead, underground and composite.

The apparatus used for the measurements was the klydonograph, and the paper gives a description of this instrument in its final form and a discussion of its working principles. The specially designed auxiliary condensers required to subdivide the line voltage are also described.

Measurements on three important transmission systems covering a year or more of continuous recording are detailed. Generally there is a large amount of oscillatory surging set up by brushing at insulators when such insulators are in a dirty condition, the over-voltage being of very high frequency and of the order of three times the normal line voltage.

The atmospheric conditions under which salt is deposited on insulators are described, and some of the records show the effect on the line voltage of a salt-laden insulator up to the time at which flash-over occurred and the line was put out of operation.

The question of porcelain insulators to meet the prevailing foul conditions and to avoid surges due to brushing is discussed. It is shown that with proper attention to design the voltage at which brushing commences can be materially increased, and it is suggested that this factor is of even greater importance than a very high initial flash-over voltage.

Introduction.

The extent to which over-voltage surges may be present in transmission systems, and their responsibility for breakdowns, have long been subjects of discussion, with, however, few or no data based on definite measurement.

With some systems on which a great deal of trouble had been experienced it became necessary fully to investigate the possibility of surges under actual working conditions, to trace their source and to find a means of eliminating them.

Consideration of the apparatus available for the purpose led to the adoption of the klydonograph as being the most suitable apparatus for the continuous records required, and therefore the paper may appropriately start with a brief description of the instrument and its working principles.

The klydonograph is an instrument for continuously recording the voltage of a system, and it will record surges of very short duration and over a wide range of frequency. It has been used in America under practical conditions for some years now, and the authors think that a description of the apparatus and its operation, with the results obtained on various British systems and the conclusions to be drawn from them, would be of interest, especially in view of the modern extension of overhead-line systems.

The principle of the instrument as devised by J. F. Peters is based primarily on the phenomenon known as the Lichtenberg figure. Lichtenberg* showed that, under electric stress, particles of certain types of powder, and particularly sulphur, would arrange themselves in a definite manner in the electric field. Later, Brown† and Trouvelot‡ discovered that the emulsion of a photographic plate was affected by electric pressure much in the same way as the dust used by Lichtenberg. Since 1888 considerable work has been done by various investigators to determine the nature of the phenomenon, but up to the present it has not been satisfactorily shown whether the effect is the ordinary one of light on the plate—with the pressure that is used there is always a slight discharge which acts in the same way as ordinary exposure of the emulsion to light—or whether it is in the nature of a rearrangement of the particles of the emulsion, due to electric stress.

The main function of the work described in this paper has been to use the instrument to record surges and not to investigate its fundamental physical properties, but consideration and a certain amount of experiment have naturally been directed to this aspect, which is discussed later.

Peters§ applied the principle to produce a surge recorder, and a full description of his apparatus and its use is given in various papers. Briefly, the instrument consists of a photographic film passing from one spool over an insulated metal drum on to a take-up spool. At the point of its passage over the metal drum three electrodes rest on the film, the electrical pressure being applied between these electrodes (three for a 3-phase system) and the earthed metal drum. The voltage across the electrodes to obtain a record is of the order of 2 000 volts (R.M.S.), and for the purpose of using the instrument on high-voltage lines dividing condensers are used. These are described later in the paper.

Later came a paper by Lee and Foust‖ in which the phenomena of positive and negative surges and their effect on the size and type of figure obtained were shown, and a method whereby a double-connected instrument could be used was given. The circuits of the two instruments are shown in Figs. 1 and 2.

The Peters instrument was first used for the authors' investigations, but after some time it appeared that improvements could be effected both to overcome difficulties in operation and to facilitate desirable experimental work with the instrument. Therefore, in the later instruments used the design was radically changed. In place of the single wide film, ordinary cinema films of standard size were used—a cheaper and better arrangement—and the instrument was of the double-pole type. Fig. 3 shows the principle. The films are drawn by the sprocket wheels between the electrodes, so designed that they can be adjusted and interchanged, and are then taken through to the take-up spools. Moreover, the instrument is designed to permit of access to the films and electrodes and so that adjustments may be made without otherwise affecting the operation, and, most important, the exposed length can at any time be cut off and removed for developing.

---

* See Bibliography, (1). † *Ibid.*, (3). ‡ *Ibid.* (2). § *Ibid.*, (7). ‖ *Ibid.*, (13).

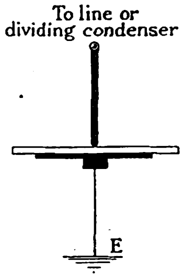

FIG. 1.—Direct-connected klydonograph.

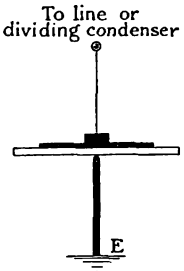

FIG. 2.—Opposite-connected klydonograph.

The type of figure obtained as a result of application of electrical pressure is becoming familiar from the American publications; and most interesting figures can be obtained with quite simple apparatus. An ordinary photographic plate in a lightproof box, placed with its glass side on a sheet of tinfoil and having a spherically ended electrode on its film side, can be made to produce remarkable figures.

CALIBRATION.

The factors which govern the size and type of figure obtained are peak voltage, polarity of the wave, and steepness of the wave-front.

In Fig. 11 (see Plate I) are shown typical examples of positive and negative figures obtained with steep-fronted waves, produced by the discharge of a condenser, and also some figures produced by alternating voltages of normal supply frequency. The negative figures obtained with the steep wave-front will be seen to be much smaller than the positive, and they are also less clearly defined. For this reason the double-electrode system has been adopted so that surges of negative polarity will be recorded on the reverse-connected electrodes as positive figures. Other observers hold that, in addition to altering the nature of the figure obtained (as shown in the illustration), the steeper wave-front gives a slightly larger figure.

For calibration purposes the authors used a 50-cycle sine wave.

It is usually stated that the klydonograph is entirely insensitive to voltages of less than about 2 500 (peak value), and in the American work the normal voltage applied to the instrument was of the order of 3 300 (peak). It was found, however, that quite definite figures were obtained at a lower voltage, although a marked increase in sensitivity occurs at approximately 2 500 volts (peak)* at normal temperature.

Working slightly below this steeper part of the curve an even more definite normal-voltage line is obtained, and it was considered important to make use of this critical point to record surges of moderate magnitude.

The difference between normal voltage and surge conditions is more clearly seen, and all this work has shown the importance of recording the oscillatory disturbances of comparatively small magnitude—small, that is, compared with a lightning stroke. A complete calibration curve is given in Fig. 4.

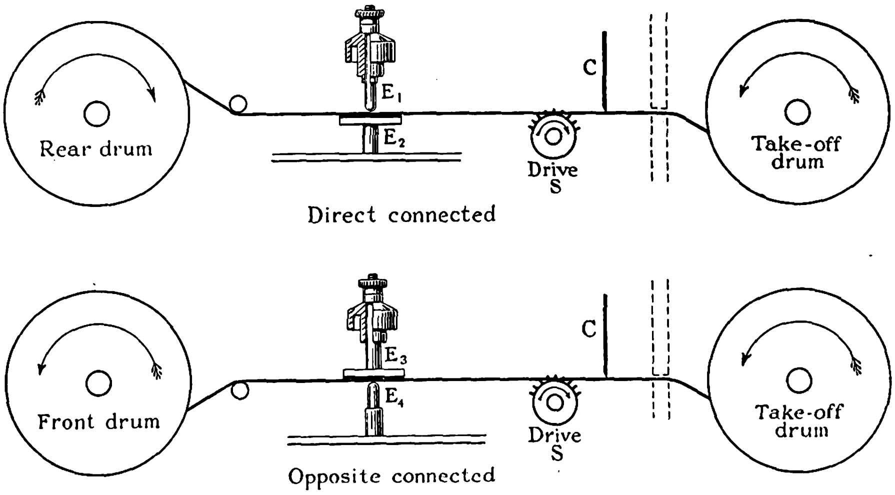

FIG. 3.

Care has to be exercised if consistent results are to be obtained, and it is important that a standardized developing process be adhered to. For their work the authors used Kodak special developer, the concentrated solution always being prepared exactly according to the instructions on the packet. This solution was diluted with tap water in the proportion of 3 parts of water to 1 of solution. The developer was maintained at 65° F. during use.

---

* It will be noted that the voltages are all expressed as peak voltages since this is the value of importance in this type of work.

The film is wound from the detachable take-up box on to a glass drum capable of accommodating about 28 ft. of film. Beneath the stand on which the drum is mounted a dish of developer is placed so that the lower part of the drum rests in the developer (see Fig. 5). The drum is then slowly revolved in the solution for 5 minutes by the clock. The drum and stand are then transferred first to a dish of water where the film is rinsed, and then to the fixing bath.

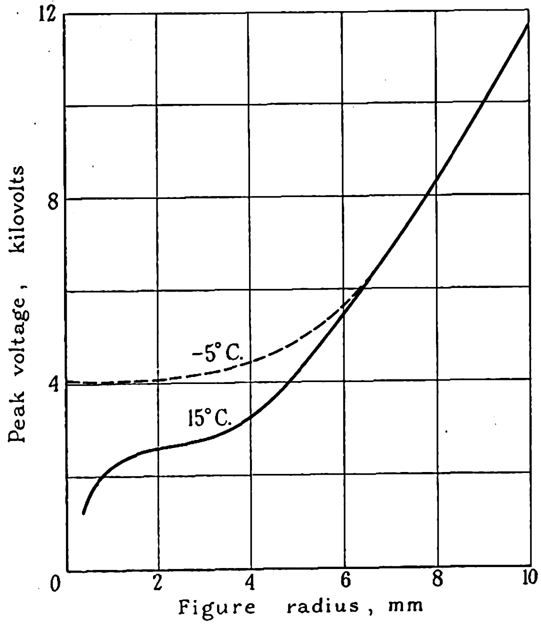

FIG. 4.—Klydonograph calibration.

SENSITIVITY OF TYPES OF FILMS.

In order to determine the most suitable type of film for klydonograph use a number of tests were made for sensitivity and general reliability of different types.

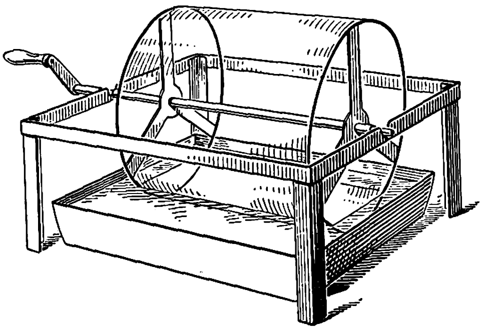

FIG. 5.—Film-developing drum.

In Fig. 6 are shown the approximate sensitivity curves of some of the types tested. It will be seen that the plates are the more sensitive.

The super-speed and par-speed cinematograph films were not very different. The latter seemed to give much more reliable results in the neighbourhood of the critical part of the calibration curve, and as these were more stable films generally they were adopted for use.

At best, however, the sensitivity of different batches of films varied somewhat, and on this account the limits of accuracy are probably not closer than plus or minus 10 per cent.

Effect of Temperature.—The upper portion of the calibration curve is practically unaffected by temperature variations, but it has been found that the lower part, in the neighbourhood of the critical point, is affected at low temperatures. Instead of the curve bending down again below the critical value it slopes straight away to zero, as indicated by the dotted line in Fig. 4. It is therefore necessary to maintain the instrument at a reasonable temperature, and in practice the temperature in the containing hut was so arranged that it did not fall much below 15° C.

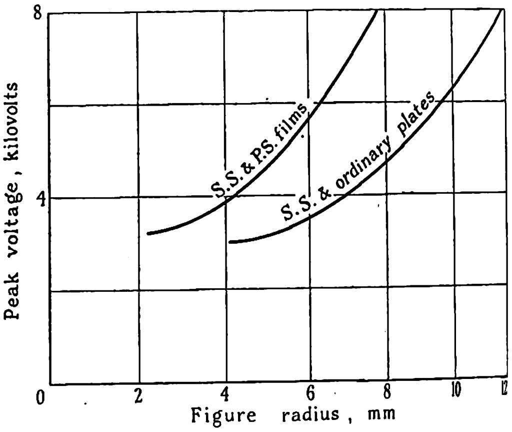

FIG. 6.—Relative sensitivities of plates and films.

Effect of Humidity.—The results obtained up to the present tend to show that the effect of atmospheric humidity is negligible, provided that moisture is not actually deposited on the film surface.

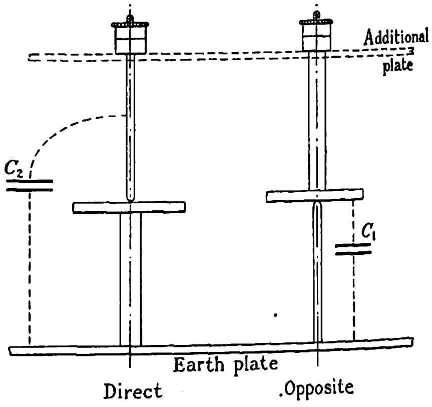

FIG. 7.

CAPACITIES OF ELECTRODE SYSTEMS.

The amount of energy involved in the operation of the klydonograph is minute, and for this reason the capacities of the 2-electrode systems must be exactly symmetrical if uniform results are to be obtained.

In Fig. 7 are shown the two pairs of electrodes and the capacities involved. It will be seen that the capacity C_1 of the live plate electrode to the earthed baseplate is much larger than that (C_2) of the earthed plate to the live point electrode. This has led, in some cases, to a smaller figure being obtained on the opposite electrode with an a.c. voltage applied through an electrostatic divider. This has been overcome, where necessary, by fitting the additional plate, shown in Fig. 7, above the live electrodes and connecting it to them, thus making the system symmetrical as regards capacity.

ELECTRODES.

A great deal of experimental work was done to determine the best shape for the end of the smaller electrode.

Hemispherical, pointed, and flat ends have been used by other investigators, but no reasons have been stated as to why any particular form was adopted.

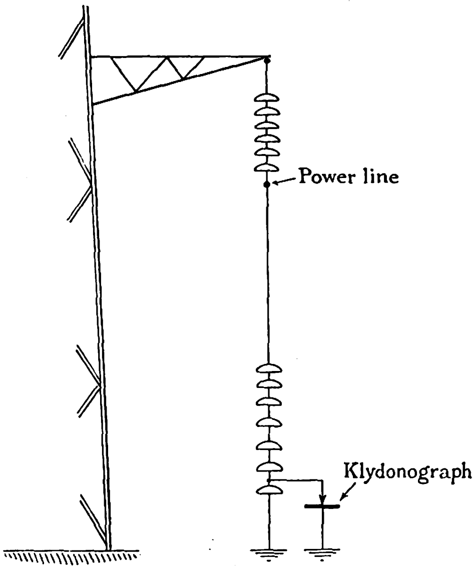

FIG. 8.

Sharp Points.—Although they gave good figures on stationary plates these points proved to be of no use when the film had to be drawn along under them, as they cut through the emulsion and gave very erratic results. In many cases the gelatine was actually torn.

Flat-Ended Electrodes.—These were found fairly satisfactory but gave such a wide normal-voltage line that small surges superimposed on it were easily overlooked. In addition, the flat electrode collects a certain amount of dust from the film surface. This dust becomes electrified and produces irregular fogging effects round the normal-voltage line, sufficient in many cases to mask the fine lines of some surge figures.

Spherically-Ended Electrodes.—These proved most satisfactory and were subsequently standardized. The line produced was of reasonable width, and it was found that by working with the normal voltage just below the critical point of the calibration curve the most sensitive arrangement could be obtained.

A firm normal-voltage line about 2 mm wide was obtained with this arrangement, and surges showed up well, above the critical part of the curve.

Diameter of Plate Electrode.—It has been found by experiment that, provided the plate electrode is slightly larger in diameter than the largest figure to be recorded, the instrument will function satisfactorily. In this case the plate is the full width of the cinematograph film.

Thickness of Ebonite under Film.—The ebonite cover to the plate electrode is not essential to the operation of the instrument; in fact better results may often be obtained by omitting it. It is necessary as a protection, however, when using inflammable films. Should the film run out, or run off its sprockets, a considerable amount of sparking will occur when the edge of the film reaches the electrode, and this sparking might ignite the celluloid of the film. The ebonite cap obviates this danger. A thickness of about 1 mm has been found ample from the safety point of view, and it makes very little difference to the size of figure obtained.

ELECTROSTATIC POTENTIAL-DIVIDERS.

Tapped Insulator String.—This is the simplest type of divider available, and one which has been much used in America. It consists of a string of suspension insulators suspended from the line with the lower end of the string connected to earth (see Fig. 8). The klydonograph is connected across one or more units at the lower end of the string. Such an arrangement works satisfactorily so long as the insulators composing the string are clean and dry. American experience has shown, however, that under wet conditions the division ratio is changed and the normal-voltage line may disappear completely in bad weather. At the same time it has been stated that the ratio remains unaltered so far as steep-fronted waves are concerned. In the present work, where disturbances of all sorts were being looked for, this type of divider was considered to be unsuitable.

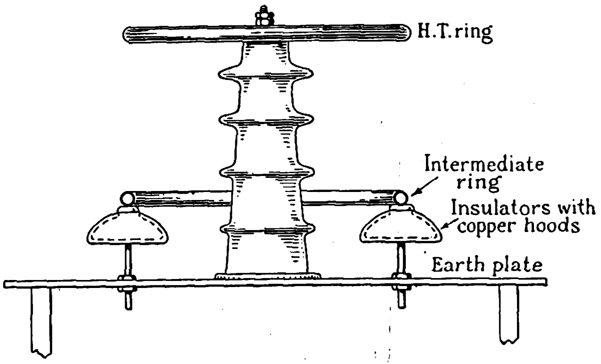

FIG. 9.

Antenna Type.—This type, which consists of an insulated aerial wire suspended beneath the overhead line, is only suitable for single-phase working, or in cases where it is not desired to trace the surges to any particular phase. It was, therefore, not considered for this work. In conjunction with capacity dividers, an antenna can be used to determine the direction of motion of a wave and its steepness, but its use in this connection is difficult owing to the direct electrostatic effects produced on the antenna from the overhead lines.

Ring Type.—This is another type used in America, and as it appeared suitable for use in this country a set of three was made up. It consists (see Fig. 9) of a large circular earth-plate about 5 ft. in diameter, in the centre of which is mounted a tall insulator supporting the high-potential electrode which is in the form of a tubular ring. A second ring, similar to the first, supported on three smaller insulators, is mounted between the h.t. electrode and the earth plate, at such a height as to give the required voltage for the instrument. This ring is adjustable for height over a limited range by means of the screw shanks of the insulator pins. The whole unit is placed on legs so as to bring the high-voltage portions out of reach of an operator working in the enclosure.

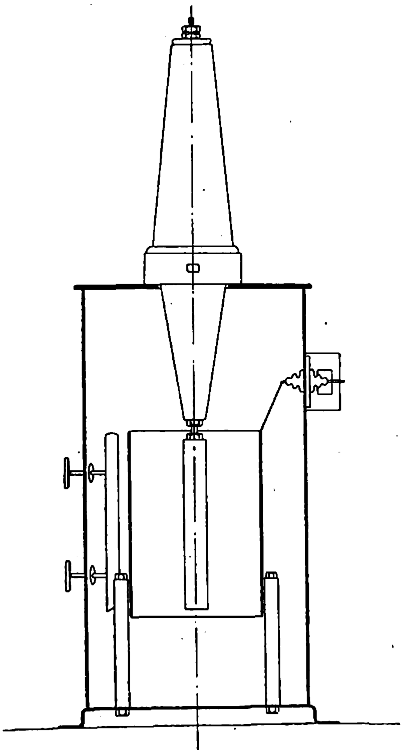

FIG. 10.

The divider in this form was used in America, but it was found necessary to make some modifications for use under English weather conditions. When the insulators supporting the intermediate ring became wetted their capacity to earth was increased to such an extent that the normal-voltage line disappeared. In order to obviate this these insulators were fitted with spun-copper hoods reaching below the bottom edge of the porcelain, and the ring itself was raised to compensate for the additional capacity inserted. With this arrangement the ring capacity was found to be sufficiently constant for reliable operation under wet conditions. Further trouble was experienced owing to the wetting of the centre insulator and to the proximity of other dividers and earthed metallic structures. This trouble was cured by blanking out the top ring so as to form a complete disc. Thus the centre insulator was protected to some extent at its upper end, and also the capacity of the whole system was considerably increased, thereby lessening the effect of stray capacities. With these modifications the dividers proved fairly satisfactory and were largely used in the earlier field work.

When, however, the effects of foul insulators became apparent, a new type was designed, since it was clear that the dividing insulator, although much longer than the line or other working insulators, was subject also to the same fouling from the atmosphere and consequently frequent cleaning was desirable.

Enclosed Cylindrical Type.—This was designed to satisfy the following requirements.

It should be:—

(1) A self-contained transportable unit.
(2) Entirely unaffected by weather conditions.
(3) Unaffected by neighbouring structures and the proximity of other dividers.
(4) Adjustable for secondary voltage over a limited range whilst under pressure.
(5) As small as possible consistent with safety of operation—bearing in mind that surges of four or five times normal voltage had to be allowed for.

The divider as finally made is shown in Fig. 10. It consists of two concentric cylinders forming the high-voltage and intermediate electrodes mounted in, and suitably insulated from, a cylindrical metal container which itself forms the earth electrode.

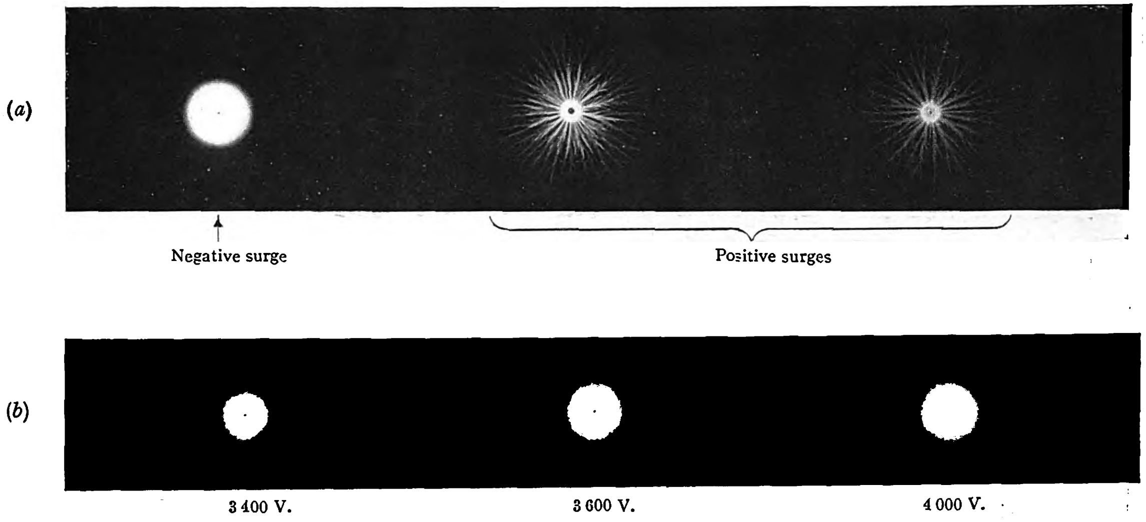
The electrodes and their insulators being thus enclosed are unaffected by weather and capacity effects due to neighbouring objects, and fouling of the external insulators does not affect the operation as they are outside the electrostatic field. It is of reasonable size and capable of being moved from place to place with moderate ease. Adjustment of instrument voltage to the extent of about 10 per cent is possible by means of the adjusting plate shown. This plate when pushed towards the intermediate cylinder increases the capacity of that cylinder to earth and thus alters the ratio of the divider. It was found necessary to ventilate and drain the containers so as to avoid condensation troubles.

A number of dividers of this type have been constructed and used with very good results.

RESULTS OBTAINED ON POWER SYSTEMS.

The first set of gear was erected in South Wales, to investigate the conditions on a most troublesome overhead line feeding a number of collieries and villages. The line pressure was 33 kV. The line was a composite one in so far as the terminal poles were in each case some distance from the substation, the current from the pole to the substation being carried by 3-core belted-type cable.

Inspection and consideration suggested that the most suitable place for the erection of the gear would be at



(a)
Negative surge
Positive surges

3 400 V.
3 600 V.
4 000 V.

FIG. 11.—Typical examples of (*a*) positive and negative figures obtained with steep-fronted waves, and (*b*) figures produced by alternating voltages of normal supply frequency.

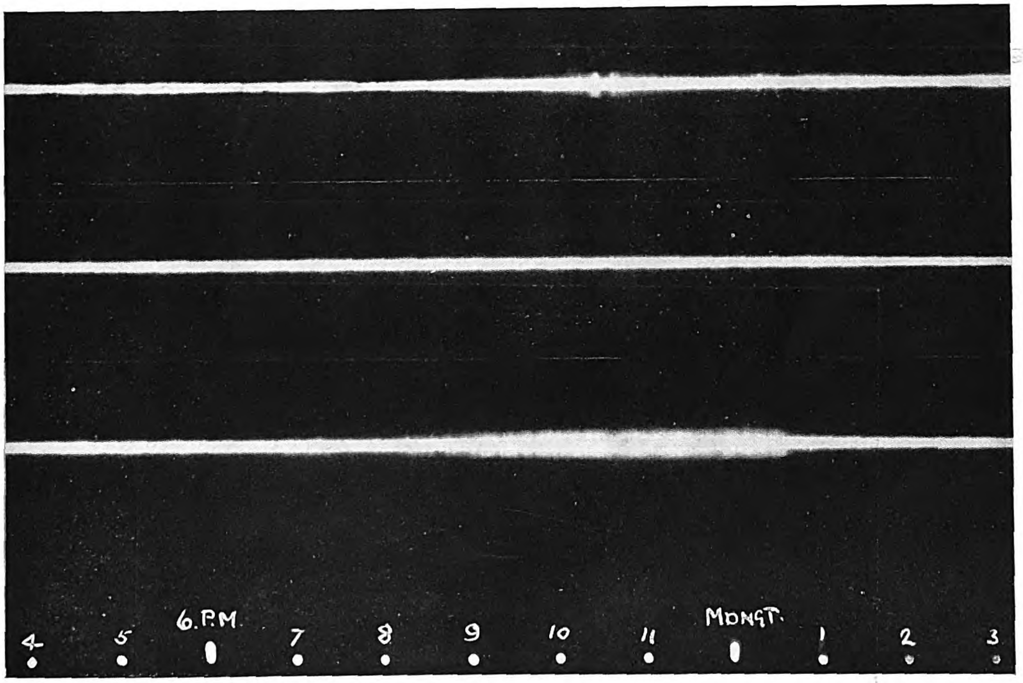

FIG. 12.

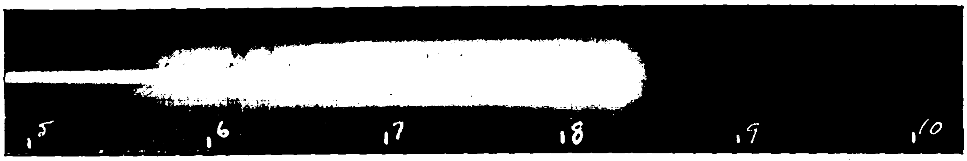

FIG. 13.

one of the terminal poles, where the abrupt change in line characteristics from the overhead line, of high inductance and low capacity, to the cable, of high capacity and low inductance, might be expected to be the point of maximum surge value, and the gear was accordingly erected on the hillside at this pole.

The results published in America, dealing more particularly with direct lightning strokes and large switching surges, led the authors to expect records of a similar spectacular nature, but the results obtained were of much milder type. The main fact that emerged was that during most nights there was a distinct thickening of the line, a sample of which is shown in Fig. 12 (see Plate I), where for a period of nearly 4 hours a series of almost continuous surges occurred. It will be seen that the effect was greatest on one phase, and that the phase recorded on the middle line of the record is practically immune. A great deal of work was done in investigating the line characteristics as affected by the running machinery at various points, and an oscillograph was installed to analyse more definitely the characteristics of the surges. These results proved that apart from switching surges of a momentary nature, with which the line was fully capable of dealing, there was no disturbance due to the machinery, and that the frequency of the surges was well above 3 000 cycles per sec.

It was not until the occurrence of a salt storm that the phenomenon was fully explained, and then it was in unmistakable fashion. By this time, owing partly to instrument trouble and partly to the desire to have an instrument that would give a more clearly defined line between normal and abnormal voltage, the improved instrument had been developed and was in service.

In November 1927, at a time when the klydonograph was in temporary use on another system, a series of shut-downs occurred during a heavy storm, or rather immediately after it. Investigation of the whole of the information available led to the conclusion that salt brought from the sea was the cause of the major part of the trouble.

Heavy brushing was noticed at the sealing ends, and it was not until the weather changed that the line would give continuous service. On being consulted, Dr. G. C. Simpson, F.R.S., who has been kind enough to give a great deal of assistance by way of explaining any possible atmospheric troubles, showed that the line trouble coincided with the somewhat rare occurrence of an abnormally dry south-westerly wind, and this led to the conclusion that a salt deposit was the trouble, not only on this but on many other lines throughout the country. This particular part of the line was 20 miles from the coast, and everything pointed to the conclusion that while with a normal moist south-west wind the salt taken from the sea would fall out quickly owing to its being wet, and therefore heavy, with the drier wind the salt spray taken up would immediately be dried by the air and be carried for a considerable distance as a fine, almost impalpable, powder. This salt impinges on the insulator in a high wind and, helped by the electric stress, adheres firmly to the insulator and does not wash off. While the dry wind continues the danger of complete flash-over is not great, but—and this is borne out by every case observed—flash-over occurs when the humidity of the air returns to a more normal value. The particles of salt then take up moisture from the air and the surface of the insulator is covered, or partially so, with a good conducting brine. If the insulator is not cleaned after the salt storm a part of the salt remains on the surface and is the cause of the surging shown in Fig. 12 (see Plate I) occurring during hours when dew falls.

Visual observation readily shows the nature of the effect on the surface of an insulator having salt deposit. During dew or a misty period large drops of water form on the surface, and as the mist disappears and the insulator dries in the sun the salt re-crystallizes and adheres so tightly that it has to be scraped rather than rubbed off.

An insulator was removed from the line some weeks after the heavy storm, during which interval it had been exposed to much heavy rain. Analysis of the surface deposit showed that there was a total amount of approximately 0·15 gramme of solid matter on the surface, consisting of chlorides, sulphates and carbonates of sodium, nickel, lead, tin and iron. Twenty-five per cent of the solids that were soluble in water were sodium chloride.

Records showing Effect of Salt Storm.—In Figs. 13, 14 and 15 (see Plates I and II) are shown some of the records obtained during and immediately after the storms in February, 1928, a period when there was much trouble with overhead lines all over the country. Fig. 13 (Plate I) shows first the comparatively clean normal-voltage line during the heavy dry wind. The point at which the line widens corresponds to that when the wind dropped somewhat and the atmosphere became cloudy. Then for some 2½ hours surging occurred, obviously due to brushing at the insulators, and at about 8.15 p.m. the breaker tripped. When attempts were made to re-set it it would not remain in and it could not be re-set until the following morning. When the switch finally held there was still considerable surging (see Fig. 14, Plate II), and at 1 p.m., when rain fell, the circuit breaker tripped out again. Then all the sealing-end insulators were scrubbed clean and the line was switched in again. Fig. 15 (Plate II) shows that the surging had practically disappeared.

It is noteworthy that the greater part of the surging occurred on one phase. That one was the nearest to the sea and the direction of the wind. Clearly the other two insulators were to a fair extent screened by the first and did not receive the same amount of salt deposit.

In November 1928 another salt storm occurred, and similar interesting records were obtained. These are too numerous for all to be published, but some of them are sufficiently different from those previously shown to be included. On one phase the oscillatory surging was practically continuous for several hours, and there were a number of oscillatory surges of comparatively short duration. Thus Fig. 19 (Plate III) shows these individual surges occurring on one phase during a period of 6 hours. Both directly and oppositely connected films gave practically the same figures, which showed that the surging was oscillatory (i.e. several cycles). The magnitude of these surges is approximately four times the line voltage, and it is somewhat remarkable that under these conditions the line was not tripped out. The same surges are shown on the other phases, accompanied by considerable brushing.

The experience during this latter storm was somewhat similar to the previous one, except that by this time the natural conservatism of the engineers in accepting the theory of salt had been somewhat overcome, with the result that now, when the line eventually came out, the insulators were promptly cleaned and the service was restored in a comparatively short time.

A large number of records on the system showed similar surging due to salt deposit, but those given above are sufficient to illustrate the nature of them.

Other Surges on this Line.—A number of other surges were recorded on the South Wales line. These were often of a minor nature, due to switching operations, but two of the more serious ones may be recorded here. Fig. 16 (Plate II) shows figures obtained on a surge due apparently to a cable failure 18 miles distant from the recorder, and Fig. 17 (Plate II) the surge produced when a phase wire fell and interrupted the current. Fig. 16 (Plate II) is of course ascribed to the cable fault, although it may be a matter of opinion as to whether the fault caused the surge or a surge brought about the fault.

Lightning.—Only one or two lightning surges were recorded, and these were due to storms some miles from the recording gear. One of these is shown in Fig. 18 (Plate II). It should, however, be noted that during the last two or three years there have been comparatively few lightning storms in this country. In fact, in South Wales the period covered by the observations was considered to be almost unique in its freedom from lightning trouble.

Midland Systems.—Similar investigations have been made on lines in the Midlands. The system in this case is a mixed one, consisting of a great deal of cable and several lengths of overhead line. In this case troubles with salt were not experienced, but some other interesting records were obtained. These results were not always fully explained, but in general the surging ceased when many line insulators had been replaced.

Curiously enough, the portion which consisted entirely of overhead line had, if anything, less surging than that which was partly overhead line and partly cable. One interesting and unexplained series of records, however, showed, during an otherwise quiet period, considerable oscillatory surges on several Sunday mornings at approximately the same time. These are shown in Fig. 20 (Plate III). The regularity of this occurrence was too marked to be accidental, and was probably due to some abnormal circuit conditions occurring at this period.

Perhaps the most outstanding record was where a cable fault occurred after a long period of surging, which latter was still evident after the fault had been repaired. Here it may be fair to say that the cable was probably injured and finally broke down as a result of many hours of oscillatory surging of comparatively small magnitude, i.e. about two or three times the normal line voltage. The day's record of one phase is given in Fig. 21 (Plate IV). The beginning of the record shows the heavy surging which had started some hours previously. This continued for about 12 hours and then ceased during the hours from noon until about 8 p.m., after which it restarted and the cable broke down. On the repair being effected the surging continued for a further 10 hours, fortunately without further breakdown.

Another case of a feeder breakdown occurring during periods of heavy surging is shown in Fig. 22 (Plate IV). Here again the breakdown and repair interrupted a long period of small oscillatory surging. Again, Fig. 23 (Plate IV) is a particularly clear example of the oscillatory surge line as compared with the normal-voltage line. The surging ceased as soon as the sun had dried the insulators. Shortly after this several insulators of the older type were changed and the cracked ones renewed. When this was completed the surging ceased.

Ice Deposits.—The atmospheric conditions known as a silver thaw, when a slight thaw with rain occurs during a frost, followed immediately by another frost, often results in the formation of ice on insulators. This is a source of occasional trouble, and, as shown in Fig. 24 (Plate IV), results in considerable surging. Somewhat similar results were found on the South Wales instruments during the same period.

Manchester.—A klydonograph set was installed at the outdoor substation at High Street, the system being entirely cable working at 33 kV. Records, continued for nearly a year, show that there is practically none of the oscillatory surging such as has been found where overhead lines form part of the system. A number of small surges were recorded and these always coincided with some switching operation. Otherwise, apart from a fault in a joint box on another system fed by Manchester, where the surge was recorded some 15 miles from the fault, the only surge of magnitude is that shown in Fig. 25 (Plate IV). This surge was clearly oscillatory and of nearly the same magnitude on both directly-connected and oppositely-connected films, and it is noteworthy that the cable system stood up to this surge of fully three times the normal line voltage.

General.—While the surges recorded have not been of the magnitude experienced by American observers, the records generally show that the klydonograph, if intelligently used, is a valuable and inexpensive piece of apparatus for recording most types of surges in overhead and/or cable systems. Possibly the results do not always lend themselves to the critical analysis and final interpretation as regards wave-shape and frequency that has been found possible by American observers, but, nevertheless, the instrument does definitely record an over-voltage due to any cause and of any frequency, and such records must lead to improvement in line operation. The records in South Wales alone resulted in an enormous saving in maintenance charges due to localization of the main cause of the trouble. In addition, the serious consequences and cost of interruption of supply for considerable periods were avoided. The authors would, however, emphasize the importance of the long series of oscillatory discharges detected by the more sensitive methods used; these are apparently of more serious import than short-time surges of greater magnitude.

With so many oscillatory surges superimposed it is hardly possible to analyse them as when a single surge of large magnitude is recorded, but for this purpose it is not necessary. From a purely technical point of view, however, it would be interesting to know more of the exact shape of the waves and of their frequency, and perhaps further experience will lead to enlightenment on these matters. Another noteworthy point is the distance which surges travel along a power line. Thus, on the overhead line in South Wales, lightning strokes were recorded some miles from the actual storm, and on the cable system in Manchester the surge set up by a fault was recorded some 15 miles away; even at that distance the value was approximately three times the line voltage.

PORCELAIN INSULATORS.

It is evident that the design of porcelain insulators for outdoor use requires a great deal of further consideration. For the pin- or suspension-type insulators the problem is fairly simple, but with sealing-ends the solution is really difficult.

The very severe conditions of fouling found in the case of the insulators mentioned have led to a thorough research into the performance of insulators both under dry and clean, and wet and foul, conditions. Whilst this work is still far from complete, a great deal has been done.

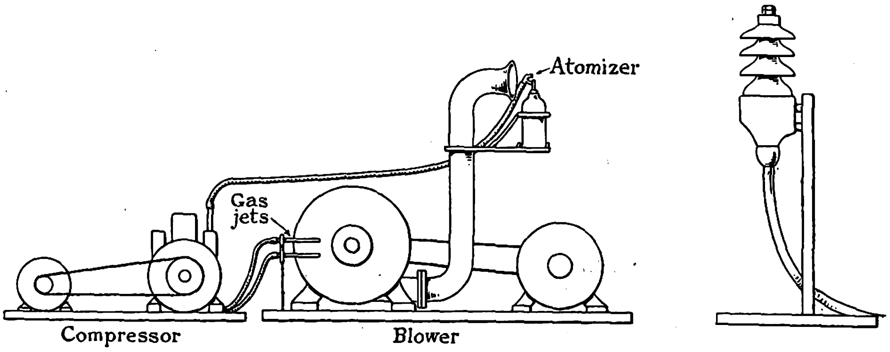

FIG. 26.

Apparatus was devised to imitate as nearly as possible the dry salt conditions previously referred to, and, after considerable experimenting, something very near to actual conditions was obtained. The apparatus used is shown in Fig. 26. A finely divided spray of salt solution is obtained from the atomizer operated from the small motor compressor to the left. The spray from this is projected into the current of air from the large rotary blower to the right, by means of which it is carried over on to the insulator under test. The drying action of the strong air-blast evaporates the water from the salt spray, leaving salt particles of minute dimensions which are deposited on the porcelain. In order to ensure the complete drying action it was found necessary, except in very dry weather, to warm the air intake to the large blower by means of the two gas burners shown.

Tests were also made under rain, fog, and salt fog, the last two states being obtained by two or more atomizers, according to the size of the insulator being tested.

It is usually found that, while pin insulators prove to be, on the whole, satisfactory in operation, the sealing-end insulators give trouble, quite severe brushing occurring at voltages less than the normal working voltage. The best design of insulator is that in which the surfaces subjected to the most fouling, i.e. the sheds in most shedded insulators, lie along equipotential lines in the electric field. With vertical sealing ends of the ordinary type this is not possible, as is indicated in Fig. 27.

Fig. 27 (*a*) shows roughly the electric field surrounding a live conductor emerging from an earthed metal cylinder (the " box " of a sealing end), the dotted lines representing the equipotentials. Fig. 27 (*b*) shows clearly how the sheds of a vertical type sealing-end must needs lie across these equipotentials. Tests involving the determination of the field diagram and surface-potential distribution of a large number of insulators of different types and sizes, and their performance under all atmospheric conditions, have shown that, although it is not possible to make any appreciable improvement to the final flash-over voltage of an insulator, the voltage at which brushing becomes serious can be materially raised. The flash-over voltage is invariably higher than the line voltage, and it is evident from the klydonograph records that the brushing is the vital factor and that improvement must be effected in this direction.

For the lower voltages the inverted type of sealing end shown in Fig. 27 (*c*) can be employed, the performance of a properly designed insulator of this type being quite good, even under severe conditions. Experiments with a vertical sealing-end have shown that it is possible to improve the brushing voltage by inserting metal sheds between the porcelain sheds in such a way that they distort the natural field and cause the porcelain sheds to lie nearly on equipotential lines. Fig. 27 (*d*) is an example of this type of treatment. Field-controlling sheds of this sort need, however, to be very carefully applied since, if improperly placed, they may bring about a large decrease in the flash-over voltage.

A great deal can be done by systematic cleaning where the line or a portion of it can be taken out of service for the purpose. The authors understand that, in those parts of America subject to alkali dust, a steam cleaning-plant is in continuous operation; as this would appear to be liable to set up small cracks in the insulators, cleaning at normal temperature would seem to be preferable. The authors have found that the vigorous use of a scrubbing brush and water is the most effective method of cleaning.

The optimistic school of thought is inclined to dismiss the subject by reference to over-insulating, but the authors are strongly of the opinion that something more than this is necessary. Even a larger insulator if left without cleaning will ultimately flash over, even if it does not shatter owing to the heat set up by the brushing, and, moreover, for a 132-kV line we are getting near to the limit of size at which single-piece sealing-end insulators can be made. It is true that very large insulators are now advertised, but they are expensive and unwieldy.

For very bad positions special arrangements might be made, and in this connection the experience in South Wales indicates a line that may be taken. The whole of the observations showed that roughly 80 per cent of the surging occurred on the line nearest to the direction of the dangerous wind, with the inference that the other two phases were to a great extent shielded by the first dividing box. Some intelligent shielding here might obviate a great deal of the trouble.

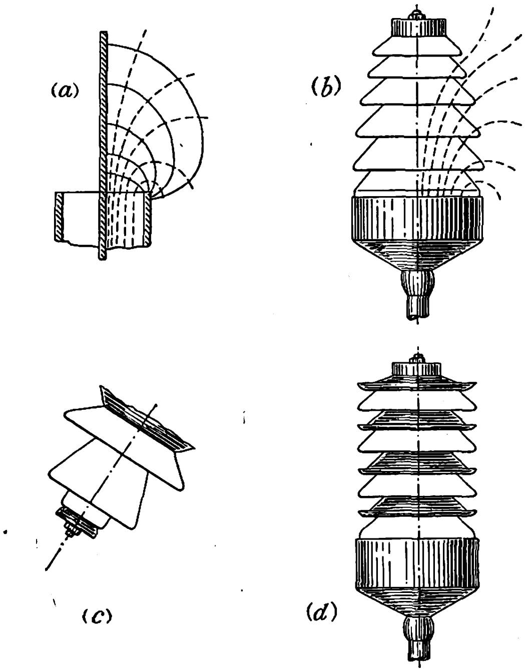

FIG. 27.

EFFECT OF SURGES ON CABLES CONNECTED TO AN OVERHEAD LINE.

While there is no definite experimental work showing that high-frequency voltage of the type recorded results in damage to the dielectric of a cable connected to the line, it must be assumed that the cable is submitted to an undue stress. Whatever the frequency of the over-voltage, it is superimposed on the normal line voltage, and in the cases shown the existence of this condition for many hours is subjecting the dielectric to a stress much larger than that for which it is designed. Although the capacity of the cable results in a considerable reduction in the amplitude of the wave, it cannot eliminate it unless the capacity is infinite, and the first part of the cable must stand up to the whole of the over-voltage.

A great deal of work has been done on this subject, but it is incomplete and is, in any case, too extensive to be included in the present paper, but probably if the length of cable is greater than one-quarter of the wave-length of the oscillatory voltage the latter may be reduced to as much as one-half of its initial value. A considerable length of cable is required, however, to effect even this reduction, and if cable is to be expected to take care of the surges a long length, very much over-insulated, must be used.

Some people hold the view that a cable having a high power factor, such as cambric cable, would deal with the surges by absorption through the wall of the dielectric, but consideration and experiment have shown definitely that this is not so. Whatever may be the merits of a cambric cable in other directions for use on terminal ends of high-voltage lines, there can be no effective reduction of surge voltage due to dielectric absorption unless a length of some miles of the cable is used. As pointed out above, however, the capacity of any cable will effect a reduction in the amplitude.

Lightning.—The question of the discharges likely to occur from atmospheric conditions has been largely discussed in American publications, in which various authors, and notably Peek,* have discussed atmospheric voltages, bound charges due to charged clouds, etc.

It is well known that a definite potential which may rise to as high a value as 1 000 volts per metre exists in the atmosphere, but the recent Kelvin Lecture by Dr. G. C. Simpson † showed that the greater part of atmospheric potential had little energy and that the only condition under which appreciable energy may be discharged is by a direct lightning stroke. This clears up the situation so far as the engineer is concerned and leaves him to solve the problem of how to deal with the lightning discharge. Fortunately, in this country we are not subject to the severe lightning storms experienced in many parts of the world, but interruptions due to lightning will and do occur. The authors do not wish to discuss protective devices, weak links, etc., but they would point out that the effects of lightning are not nearly so serious as the other difficulties enumerated above. A lightning stroke almost invariably causes the line to trip out; one or other of the insulators flashes over and a circuit breaker operates. Apart from the short interruption, however, the line is usually undamaged and can be put back into service almost immediately.

There is, however, one point to be made in connection with any system of spark gaps or weak-link insulators. For the protection of transformers and other apparatus it is essential that the protective device should operate at a definite voltage and be unaffected by weather conditions. This is hardly possible unless any gap on which operation depends is definitely under cover.

ACKNOWLEDGMENTS.

In the course of this work in several fields the authors have had to call on a number of people for help, and they gratefully acknowledge the keen interest taken and

---

* See Bibliography, (19) and (23). † *Ibid.*, (17).

the great assistance given by everybody concerned. In particular, Mr. J. W. Burr, borough electrical engineer, Swansea, and his assistant, Mr. A. Jarratt, rendered invaluable help in the earliest and most difficult work carried out in South Wales. Dr. Simpson was consulted on possible weather disturbances and freely gave full advice and information on the atmospheric side of the subject, while Mr. J. C. Poole carried out most of the work of maintaining the stations and obtaining the records, his help being invaluable. Thanks are also due to Messrs. Callender's Cable and Construction Co. for permission to publish the results.

APPENDIX.

THEORY OF OPERATION OF KLYDONOGRAPH.

Although the klydonograph has now been put to a considerable amount of use, comparatively little work seems to have been done with a view to explaining the physical phenomena connected with its operation. An interesting series of experiments conducted by Magnusson * has led him to conclude that the image on the plate is actually due to light emitted from the discharge. In support of this theory he gave the following experimental results:—

(*a*) If the photographic plate be covered by an additional glass plate and the point electrode placed on this the figure produced is blurred. This fact, which has been confirmed in this investigation, was explained as being due to diffusion of the light by the intervening glass.

(*b*) With the same arrangement as above, and a sheet of black paper between the glass and the plate, no figure is produced. The authors' tests made to confirm this result led to the discovery that the screening effect only occurred when the paper was in good contact with the photographic plate. In places where it had been lifted, a portion of the figure was obtained. It was therefore thought possible that the effect might be due to the semi-conducting nature of the paper used (such papers being often of the carbon type). To test this the black paper was replaced by some red wax paper—definitely non-conducting—and similar results were obtained.

As a further test to ascertain whether light is the direct cause of the image, the authors took additional figures as follows:—

(1) With a plain glass plate between the photographic plate and the point electrode, as before.

(2) With a photographic "safe-light" glass instead of the clear glass. The "safe-light" gave complete screening.

A further useful experiment consisted in the application of steady d.c. potential to the klydonograph. This was done by means of a small high-voltage d.c. machine shunted by a condenser to smooth out any possible commutator ripple. Under these conditions no records at all were obtained.

From this it is clear that the actual electric stress is not the cause of the figure, and the screening experiments indicate that the image is due to a radiation capable of being absorbed by certain light screens. Whether this radiation actually falls within the visible range is most doubtful. McEachron * claims to have produced figures even when the voltage took 20 minutes to reach its maximum. He was, however, using much thicker plates and much higher voltages. The authors are of opinion that in his experiments some ripple of which he was unaware was present and caused the figure.

It would appear possible that the effect of applying a voltage wave to the instrument is to project electrons from the electrode over the surface of the plate. The acceleration of these electrons would depend on the peak-value and wave-shape, and a radiation corresponding to the acceleration would be set up. Such a movement of electrons might be considered to be somewhat similar to cathode rays, and a further experiment by Magnusson supports this theory. He showed that klydonograph figures taken under reduced air pressure were considerably larger than those at atmospheric pressure, and it is known that the range of a cathode ray becomes less the more gas is present in the tube.

It has been noticed in the American type of instrument, in which the film is drawn over a curved surface, that the figure produced is not circular but is of smaller radius in the direction of curvature. This again might be explained by the electrons being projected across the plate at the point of contact and flying off tangentially. If this is the case, it shows also that the range at which the radiation set up will affect the photographic film is very limited.

There appears to be evidence that a certain amount of light or ultra-violet radiation occurs during the formation of the figures. The effect is noticed only if moderately high instrument voltages are being employed. For instance, if an a.c. voltage is left on a stationary film for some time (half an hour or so) the dense black figure obtained is surrounded by a haze of fogging (similar to that associated with light leakages in a camera) extending for some inches.

The difference in the type of figure obtained with positive and negative surges has already been referred to and can probably be explained as follows. In the case of negative figures the electrons are projected outwards from the electrode in all directions, giving a uniform type of radial figure. The slight irregularities often observed are undoubtedly due to small projections, etc., on the electrode. With positive figures the electrons are drawn towards the electrode, the positive ions thus formed creating conducting channels through which the flow is continued in a manner similar to the formation of a lightning discharge, as described by Dr. G. C. Simpson † in the 20th Kelvin Lecture.

A further experiment which it is interesting to note in this connection is that made by G. L. Addenbrooke.‡ A point electrode was suspended about 1 in. above the surface of a shallow bath of oil, the bath having a metal rim. When the electrode was charged to a high potential, radial splashes were produced on the surface of the oil. The formation of these splashes for positive and negative electrification was almost identical with the corresponding klydonograph figures obtained, except, of course, that a much higher voltage was required for their formation.

Discussion before The Institution, 10th April, 1930.

Mr. E. B. Wedmore: The authors have dealt with disturbances on a particular system. From the point of view of the Institution they have introduced a much larger problem. Members are responsible for electric generating and distributing plant to the value of about 100 million pounds, the whole of which is subject to these disturbances. We are still largely ignorant of the nature and extent of these phenomena, mainly because appropriate methods of experimental investigation have been lacking in the past. We have fallen back upon elementary ideas of induction and capacity, and upon the appropriate formulæ for transients. Having predicted that certain actions would take place, we have been quite pleased when our predictions have been justified. But a formula will never give any information other than that which is put into it, and we have neglected the experimental work necessary to furnish the constants for the formulæ. The phenomenon described in the paper has in the past been more important, perhaps, in the United States than in Great Britain, on account of the very large overhead distribution systems in the former country. Hitherto we in this country have grumbled about phenomena which we did not understand, but we have not been driven to make such investigations as that described in the paper—a line of investigation which should, I think, be pursued. Electric waves are travelling day and night over this 100 million pounds' worth of plant and detecting all its weaknesses in a wholly destructive manner. We cannot gain too much information about the phenomenon, and we know far too little at the present time. British standard tests for the insulation of apparatus are based upon factors inadequately correlated with the conditions which the apparatus has to withstand. In dealing with the phenomena of circuit breaking we do not have to deal solely with the normal line voltage of the system. We may be circuit-breaking on systems which are at the same time continuously subjected to surges resulting from small amounts of energy. This energy may not be sufficient to show on the balance-sheet, but it represents high voltages which manifest themselves across the terminals of the circuit breaker and affect its performance. Surge phenomena are even more important in connection with insulation, as authorized undertakers incur expenditure amounting to about £500 000 per annum as the direct result of damage due to insulation failures. Such failures are, I think, largely connected with these over-voltages, which are constantly affecting the insulation in a destructive manner. If members of electricity committees could only see the electric waves travelling on their systems, they would realize the importance of the problem. The experimental method described in the paper is not in itself a new one, but certain of its details are novel. It enables us to make a fairly accurate estimate of the range of high voltage, and also to obtain a distinction as to whether we are dealing with an impulse or with an oscillatory discharge. It lacks in precision, however, when measuring the frequency of the disturbance. Oscillograph films run at high speed have to be used instead, and the cost of the equipment is very greatly increased. We should consider whether it would not be practicable, by some not-too-expensive addition to the apparatus described, to record the frequency of, at any rate, those phenomena that are constantly repeating themselves. It might be possible to use a group of such devices each tuned to respond to a wide band of frequencies and together covering the whole range of frequencies in question, and to observe at which of them discharges are obtained under any particular condition. A calibration curve for the apparatus itself has been shown and two curves taken at two different temperatures have been obtained. The one for the higher than atmospheric temperature was straight over a much larger range than the one for the lower. I should like to know whether the authors have worked at higher temperatures still, which, while perhaps not convenient for their work, might be suitable for laboratory work. For so far as the indications go, the straight part of the curve might be extended if the temperature were raised, and the utility of the apparatus would thus be increased. With regard to the calibration of the apparatus, the authors give a figure of 10 per cent for the probable error: this, if obtainable, is a very good value for work of this kind. I should like to have more information about the calibration of the instrument itself, and also of the potential divider used in connection with it. I am uncertain whether, when the instrument itself is discharging, the energy taken by it disturbs the distribution of the potential across the condenser arrangement, or whether such action is negligible within the 10 per cent error range. Has any estimate of the amount of this energy been made, and does such energy affect the initial calibration of the device proper? The subject of the authors' paper is overdue for consideration in this country. The Electrical Research Association now has funds which it could allocate next year to work of this kind. Apart from the surge problem, the wide question of testing insulators subject to the weather conditions referred to is already being considered, and I hope we shall soon make progress in the solution of that problem also. We should welcome any communications from members interested in the investigation of surge phenomena.

Prof. E. W. Marchant: The results obtained by Magnusson with reduced air pressures were, I think, taken over a limited range, and I should be glad if the authors could give some actual values for the increase in size of the klydonograph figure which is obtained when the air pressure is lowered. With regard to the temperature effect, is this mainly due to alteration in the sensitivity of the film at the lower temperatures, or to an alteration in the discharge? In connection with the surges observed, was an earth wire fitted to all the lines on which very high pressures were obtained? The ordinary method of protecting against lightning is to have an overhead earthed wire connecting the poles, and I presume that this arrangement was adopted on these lines, and that it was in use when the test was made. The surge pressures that have been observed are alarming from the point of view of operating engineers, as they are very much higher than those which would be anticipated. I think that the chief operating difficulty to be dealt with is that of finding a method for preventing these surges from causing damage in the stations. Mr. Paton, of the North Wales Power Co., recently told me of his experience with regard to surges on their system. The normal method of protecting the transformers is by means of thickened insulation at the point where they are connected to the overhead line. This tends to prevent the surge from coming back into the transformer and damaging or breaking down the insulation. A very large number of the faults that have occurred on the North Wales Power Co.'s system, however, have been found at the earth end of the transformer, i.e. at the other end of the winding. A surge presumably travels along the line, from the point where the arc or flash-over occurs, but it travels along the overhead line and also through the earth. Because of this latter action, the apparently anomalous result of a very high pressure on the first few turns at the earth end of the transformer is obtained. From the point of view of protection, therefore, it is as important to thicken the insulation of the turns of the transformer at the earth end, as it is on the high-pressure side of the system. For a number of months we have been making investigations on the strength of insulating materials when subjected to high-frequency discharges. Very little information seems to be available regarding the electric strength of insulating cables at anything above quite low frequencies. About three years ago Goebeler showed that the electric strength of fibrous insulating materials at frequencies of the order of 100 000 or 200 000 cycles per second was negligible compared with that at 50 cycles. It is fairly well known that at 100 000 cycles the electric strength of a material like glass is about 0·3 of the corresponding value at 50 cycles. Ebonite shows similar characteristics, but for fibrous materials the ratio is much smaller, i.e. the electric strength at 50 cycles is much greater than it is at the higher frequencies. Any information which the authors are able to give on this subject will be of value. It is clear that, if adequate protection is to be provided against the dangers that may arise from the presence of high-frequency surges, insulating material of far greater thickness than would otherwise be necessary must be provided at points where such surges are likely to attack the distribution system.

Mr. N. Herwald: That climatic conditions have a great deal to do with the efficient maintenance of a transmission line is, I think, well known, but I do not know whether specific reasons exist to explain the occurrence of surges in particular localities, such as those which occurred on the South Wales line and are described in the paper. I am interested in the question of surges in composite conductors, and as this is an important factor in connection with over-potential in lines it seems probable that voltages in the overhead section will cause surging to take place. The surge would travel along the line until a cable was met with, and the comparatively high inductance of the cable section with respect to the overhead section would tend to make the potential build up at the junction point. I think that the question of wave-shape analysis is only one of time, now that a start has been made in the use of the klydonograph in this country.

Mr. B. L. Goodlet : The main thesis of the paper is that the discharges which occur on dirty insulators, apart from damaging the insulators themselves, react on the transmission system, producing therein voltage surges of dangerous magnitude. I do not think that this suggestion has been put forward before, and if it is correct it will produce some very radical changes in our ideas on the subject. I will accordingly discuss briefly (1) the origin and peculiarities of the insulator discharges, and (2) the nature of the disturbances so set up. Troubles due to fouling of insulators are encountered in many parts of the world. The mechanism in every case is the accumulation of a surface deposit on the insulator which when dry has little effect but when damp causes surface discharges and a large reduction in the spark-over voltage. The power dissipated in these discharges is often quite considerable, and, as the resultant heating is very localized, cracking of insulators often occurs. In the cases investigated by the authors the troubles seem to have been due mainly to salt. The insulation of coastal lines is, of course, a traditionally difficult matter, but I am of the opinion that the atmospheric conditions encountered in some of our industrial districts will probably be equally difficult to deal with. The authors find that salt is not carried far inland except by a dry wind, that the deposit is localized towards the windward side, and that the use of insulators with deep vertical sheds, such as the inverted sealing-ends mentioned, minimizes the trouble, as the salt accumulates mainly on the exposed vertical surfaces and not to any great extent inside the insulator. In a smoky, industrial atmosphere, however, the suspended particles are very small and light and, owing to their tar content, they are also very sticky. The slightest air eddy carries them right up inside the insulator, where they stick even to the under surfaces of the sheds. On surfaces exposed to rain the non-adhesive and soluble components of the deposit are soon washed away, so that the film on these surfaces grows only very slowly. On the protected surfaces where this washing does not occur the deposit accumulates very rapidly. In one particular case investigated by us the monthly increment on the shielded surfaces was found to be about 0·5 milligram per cm^2— a figure which is nearly 60 per cent of the mean monthly precipitation of total solids for the locality as measured by the standard pollution gauge, which retains everything falling into it. A few months after this particular line was put into service the insulator discharges were sometimes so severe that policemen on night duty rang up to say that some of the towers were on fire. It is quite obvious that operation under such conditions soon becomes almost impossible. I am inclined to think that this trouble of atmospheric pollution is going to be our national trouble, just as lightning is in the United States and earthquakes in Japan. At present, however, no solution of the problem seems to be available, apart from the washing of the insulators at frequent intervals. I agree entirely with the authors' remarks about the futility of over-insulation; really serious trouble will not be cured in that way. There are about a dozen different insulators designed for use in foul localities. Most of these depend for their efficacy upon the shielding action of deep petticoats, and where the impurity is heavy and carried by a side wind this may be fairly effective. I do not know of any insulator the interior of which will keep clean in a really smoky atmosphere. The damaging effects of discharges on the line insulators are, of course, well known. The authors' contribution to the subject is the discovery that these discharges produce, in the system, surges of sufficient magnitude to endanger connected apparatus. The fact that these discharges do produce oscillations is, of course, well known, and the problem of radio interference from transmission lines has been studied quite extensively. I am, however, a little surprised to learn that the magnitude of these oscillations is as great as the authors state, and I cannot help wondering whether a slight error has not crept into their measurements. If I understand the matter correctly, the authors calibrated their klydonograph by measuring the size of the figures produced by various 50-cycle voltages, and obtained in this manner the curve shown in Fig. 4. They then assumed that this relation remained the same whatever the frequency of the voltage applied, so that the voltage of the high-frequency disturbances observed could be deduced from the measured dimensions of the figure and the 50-cycle calibration curve. Actually, however, the figure produced by a high-frequency voltage may be considerably larger than that produced by a 50-cycle voltage of equal magnitude, and, if this frequency effect is neglected, voltages of high frequency would appear to be of much greater magnitude than they are in reality. For this reason I am inclined to doubt the figure of 3 times working voltage given in the paper for the amplitude of surges produced, unless the authors have checked this value by an independent method. I should be surprised to learn that any voltage in excess of twice normal was, in fact, present. In this connection it is a pity that the authors can give us no idea of the frequency of the disturbances set up. Although the tuning bands would probably be quite wide I think that wavemeter measurements would probably give the required information, and this would at once settle the question of the frequency error I have mentioned. If the frequency of the oscillations proves to be only a few thousand cycles this error will probably be quite small. The final point I should like to make is the importance which the authors' investigations impart to apparatus testing with damped oscillations. In surge testing at the present time the fashion is set strongly towards the use of impulsive voltages. The authors show that damped oscillations of appreciable magnitude may be maintained in a system for long periods of time; the behaviour of apparatus when subjected to this type of disturbance is therefore a matter of considerable interest.

Mr. N. E. P. Harris : If the statements made in the early parts of the paper were accepted at their face value, it would be hard to believe that any transmission line, either in an industrial or in any other area where salt is prevalent, could go on working at all. We have to remember that transmission lines in some of the most difficult parts of the British Isles have been giving satisfactory service for the past 20 years, at any rate. In this connection I was interested to note the definite statement made by the authors that voltages of the order of 4 times the normal working voltage have been observed not only for short periods but even for 8, 10 and 12 hours. Judging by the information given in the paper, it is remarkable that frequent spark-over did not occur under these conditions. I have based the following calculation upon a typical example and have used the authors' figure of 4 times the working voltage. I think that the voltage which I have selected is the same as that in South Wales on the transmission line under discussion. Transmission-line engineers in this country often use an insulator larger than the British standard design for any particular voltage rating. Let us assume that a normal 50-kV insulator has been used on a 30-kV line, which gives a maximum value of $(30/\sqrt{3}) \times 1\cdot 4 = 24\cdot 5$ kV to earth. As is pointed out in the paper, it is always the maximum value which is recorded. The spark-over under rain of a British Standard 50-kV insulator is 125 kV (maximum value 177 kV), and 4 times the maximum value of the line voltage to earth is 98 kV. From experiments in the laboratory with artificial salt deposits obtained in a way very similar to that employed by the authors, the reduction in the wet value is of the order of 30 to 50 per cent. Assuming as an illustration the intermediate value of 40 per cent, I should expect the 177 kV on the British Standard 50-kV insulator to be reduced to about 50–60 per cent of its normal value. This indicates that the figure at which I should expect spark-over to occur under the given conditions would be of the order of 105 kV. A comparison of this with the value of 98 kV, which I assume is about the voltage obtained, leads me to think that not only the sealing-end insulators but also the pin insulators (assuming that pin insulators were used) were actually *on* the point of sparking-over. I was interested in the authors' remarks on the subject of insulator design; I regard the statement that "the best design of insulator is that in which the surfaces subjected to the most fouling, i.e. the sheds in most shedded insulators, lie along equipotential lines in the electric field," as pointing in the same direction as Mr. Goodlet's statement made at the Institution rather more than a year ago. This was to the effect that the minimum of disturbance of the electrostatic field will occur when an insulator is so shaped that deposits form on those surfaces which are equipotential surfaces. I conclude that the authors really had in mind the question of the disturbance of the original field. While agreeing with the principle, I still hold the view that the ability of an insulator to give good service under difficult conditions depends upon the length and efficiency of the paths which separate the equipotential surfaces. I am not in agreement with the statement that "although it is not possible to make any appreciable improvement to the final flash-over voltage of an insulator, the voltage at which brushing becomes serious can be materially raised.' 'If the voltage at which brushing starts were increased, I should be surprised if the voltage at which ultimate spark-over takes place were not increased also. I refer here not to the spark-over of a new, clean insulator, but to the spark-over of an insulator which has been the subject of deposits. In connection with the statement that the best performance is obtained when the surfaces of the sheds follow the equipotential surfaces, I re-read a paper * presented by C. L. Fortescue and S. W. Farnsworth in 1913. The authors had no idea of the troubles which were to come through the fouling of insulators. They put the same idea forward, however, in rather a different way. The body part of their insulator was shaped like an inverted pineapple, so that it followed the flux lines of the electrostatic field, whilst the sheds were at right angles to them and approximately along the equipotential surfaces. The so-called "Faradoid" insulator was developed upon the recommendations of this paper, but it has not been a conspicuous success under conditions of polluted atmosphere. It may be that the fact that it has sometimes failed has nothing whatever to do with the correctness or otherwise of the design. The ideal shape from electrical considerations may have been advanced without regard to the necessity of providing an insulator which will give good service under ordinary conditions of atmospheric pollution. Even when severe and frequent salt storms are experienced, as described in this paper, the insulators should possess that margin of security which will enable the necessary periodic cleaning to be carried out at convenient times separated by reasonable intervals.

Mr. T. N. Riley: The authors have demonstrated clearly that discharges over insulator surfaces are responsible for the surging effects on overhead lines. They have also recorded a number of surges on lines in cable systems without suggesting any definite cause in those cases where there has been *no* fault. It struck me that discharges in the interior of a cable, such as may occur on high-voltage cables without equipotential sheath, might be responsible for similar surges on cable systems. If so, such surges would occur during periods of light load when voids are most likely to be formed. Some of the diagrams given in the paper seem to support this view. Fig. 20 shows that on three Sunday mornings—periods at which a feeder cable is probably running at its coldest—the surges arise, disappearing again later in the week. It is hardly likely, I think, that exactly similar atmospheric conditions would occur on three successive Sundays. Again, Fig. 21 shows that there is heavy surging from 12 midnight. This begins to die off soon after 9 a.m., has practically disappeared by noon, and does not recur until the evening. I believe the authors suggested that the gap in the curve indicates a fault at about 8 p.m., but the repair of this fault does not appear to have affected the surge. The cable having cooled down, the surge again commences. Fig. 22 also exhibits similar characteristics. It is possible that a breakdown and repair at one point of the cable might still leave distributed voids along its length, and that these might still initiate surges. Such surges would not necessarily be very great except where overhead-line sections existed, when their inductance, together with the cable capacity, might give rise to resonance effects. It would be of interest if the authors could add to these diagrams some statement of the period of the year to which they refer, and of the current loading of the cables during the periods recorded. On page 1485 it is stated that no records were obtained by the application of steady d.c. potential to the klydonograph. I cannot quite harmonize this statement with the explanation of the action given—that of an electron discharge, which should occur equally well under d.c. potentials. I have therefore made some tests with a view to obtaining a check as to whether such action did, in fact, occur. The apparatus was very simple, merely consisting of a pin put through the top of an ordinary negative box so that it touched the film of a plate resting with the glass side on a sheet of tinfoil. Voltage was applied between pin and tinfoil from an accumulator battery giving up to 8 640 volts. With the needle positive the figures were similar to those of the authors' Fig. 11. With the needle negative the discharges were of the same type as those described by the authors, with the exception that the higher voltages produced a few streamers round the central nucleus. [Mr. Riley here exhibited two slides showing the results which he had obtained at various voltages.] It has been stated that the diagram obtained varies according to the steepness of the wave-front. McEachron's tests show relatively weak evidence for variation of the radius with steepness of wave-front. The small increase in size with increased steepness of wave-front could quite well be due to partial reflection at what amounts to the open end of a circuit causing an effective rise of potential. Such a reflection effect might be expected to be a maximum when the rate of rise of voltage is greatest; this may be a phenomenon similar to the one obtained by Mr. Goodlet at high frequency, because under such conditions the rate of voltage-rise would be more rapid than at low frequencies. It would be of interest if the authors would give the results of any investigations which they may have made on this point, with a view to explaining the mechanism of the action.

---

* "Air as an Insulator when in the Presence of Insulating Bodies of Higher Specific Inductive Capacity," *Transactions of the American I.E.E.*, 1913, vol. 32, p. 893.

Mr. A. G. Collis: The paper appears to be confined to a description of the klydonograph and the effects of brush discharges over insulators. Whilst I have no experience of the method adopted, I am doubtful at the moment of its mathematical accuracy in the determination of design. Is it not true that its adjustment ratio, being variable by the situation of the cylinders, is affected by capacity to earth? I should prefer the oscillograph, which would enable the physical relations of the circuit to be determined. An analytical assumption from such tests as those described is limited, owing to the absence of details of the transmission system under review. Was the system earthed or insulated? The effect of a brush discharge or a surge attending a fault on an earthed system is of greater dimensions than that produced on an insulated system. If the insulated transmission is large, so that the electrostatic capacity between conductors and ground is high, a proportional charging current will flow into the fault. Again, the potential between the other two conductors will be 1·73 times its normal value, with a corresponding increase in charging current. Although the question of the relative merits of earthed and insulated systems is not discussed, it has a bearing on the tests described and the subject of the paper. The absence of oscillograph records makes diagnosis difficult, as a fault to earth, according to its resistance, naturally distorts and affects the power factor of the system. Technical particulars such as the impedance and reactance of the equipment would also be of some assistance. With regard to the condition for resonance, is it possible for the self-induction and capacity to be so proportioned that the current flowing when the capacity is short-circuited equals that flowing when the self-induction is short-circuited? The construction of any transformers or synchronous condensers which may be connected to the line affects the situation. The former may be of the star-star type for the sake of economy, or they may be provided with a tertiary winding to avoid trouble due to the third harmonic. I hope that the authors will include in their reply some information regarding these points. The application of reactors also affects the voltage surge on the line. Under normal conditions there is no voltage-drop across the reactor, but abnormal conditions give rise to a tendency for such a voltage-drop to be built up, and the energy from this is dissipated in the resistance of the reactor circuit. If an oscillograph record had been included in the paper it would have been possible to determine whether or not the wave-form was symmetrical with twice or three times its peak value, and whether in consequence the electromechanical stresses of the latter were directly proportional to the square of the current and inversely as the distance between transmission phases. I have conducted a large number of tests on surges, chiefly on those introduced by the rate of change of electrical phenomena, and in the early days I used a spark-gap to earth. It was then supposed that the operation of closing the circuit of a long underground transmission line produced high electrical pressures which broke down the end-turns of stator coils. These were reinforced by insulation, and at that time surge resistances were employed to limit the pressure when switching in, but such precautions were not entirely justified. In regard to the design of transformers, the end windings are at present reinforced in order to preserve a high factor of safety, and for this reason we must first consider the effect of an alternating pressure upon a conductor with inductance and capacity in parallel. If the applied pressure is constant, the current taken by the capacity is directly proportional to the frequency, while the current taken by the inductance is inversely proportional to the frequency; the particular frequency at which these two currents are equal is termed the resonant frequency of the combination. At frequencies below that of resonance the current taken by the inductance is in excess of that taken by the capacity, while at frequencies greater than that of resonance the reverse condition holds good. If the alternating pressure is connected to the inductance and capacity in series, the same current flows through each but the pressures across them are in opposition. The current is initially limited by the inductance and eventually by the capacity, so that the e.m.f. oscillates from a maximum across the inductance to a value 100 per cent in excess of the applied pressure across the capacity, and so on. My experience is that a large number of breakdowns result from defective switchgear, the chattering or unequal alignment of the contacts of which produces high-frequency waves which impinge upon the transformer. The general practice is to close the primary circuit first, and this to a certain extent eliminates distortion of the windings due to heavy current-rushes. When opening the primary, however, excessive potentials are imposed upon the circuit, particularly if the flux intensity drops with a rapidity greater than the normal cycle rate. Instability of the arcs formed on breaking circuits is productive of high-frequency pressure oscillations, and it is for this reason that oil circuit-breakers are preferable to air-break switches. These points are mentioned in order to show that the brush discharge is a comparatively small matter connected with the other transients on the circuit. It is comparatively easy to design an insulator of such a potential gradient removed from earth potential as will eliminate brush discharges or ionization, but it is not easy to meet the conditions of transients inseparably bound up with the phenomena attending transmission. If we could eliminate the power-factor effects of the loads connected to the system, we should be able to reduce the consequences of over-voltages resulting from changes in the circuit conditions.

Mr. F. E. J. Ockenden: The design of the condenser used by the authors as a voltage divider is of interest since it is not easy to design a condenser of this type which will maintain its accuracy under varying conditions of temperature and atmospheric humidity. The form of insulator used for the low-tension end of the condenser as shown in Fig. 10 is, in my opinion, unsuitable for the purpose. The capacity current available at the low-tension terminal is only of the order of a few microamperes, and a very minute leakage through the insulator may represent a large proportion of the total current, and therefore a large error in the voltage ratio. In practice this leakage may take two forms. The first and less serious is that resulting from direct leakage over the surface of the insulator. If, however, the surface is long and is kept reasonably clean the leakage is small, and is in any case in quadrature with the capacity component, so that its effect should be extremely small. The second form of leakage is the result of a conducting film forming on the surface of the insulator and linking up with the earthed case to which the insulator is attached. This film acts as an electrode surrounding the leading-out terminal, and capacity currents induced in it flow directly to earth through the metal case, thus causing a leakage current to flow which is both of considerable magnitude and in phase with the main capacity current. In Fig. A the capacity leakage film is shown by the dotted line. It will be noticed that it is not affected by the length of the insulator, and is but little affected by the "amplitude" of the corrugations if these are shallow, as shown in the sketch. The resistance of this film is of course considerable; thus it is only effective for a small distance along the insulator, but this distance is very variable, depending on the humidity of the surrounding atmosphere. The film is, moreover, very tenacious and it is my experience that no ordinary dry cloth, even when warmed, will completely remove it. An effective solution to this problem may be obtained by constructing the insulator with corrugations the sides of which are vertical, the first of them being mounted very close to the metal case. Fig. B shows the general arrangement of such an insulator. The position of the conducting leakage film is shown by the dotted line. It will be noticed that variations in the length of this film tend to occur only up and down the sides of the radial fin, and consequently these variations will have little or no effect on its capacity to the leading-out conductor. Condensers used as potential dividers for operating electrostatic voltmeters have shown a consistency of nearer than ½ per cent even under the most adverse conditions when fitted with this type of insulator on the low-tension end. The authors' remarks on the origin of the difference between the records obtained from positive and from negative surges remind me that some while ago I was investigating the difference between the positive and negative electrodes of an ordinary d.c. spark-gap of the order of about 1 mm in length, such as the gap in a magneto-operated sparking plug. As will be seen from Figs. C and D (see Plate IV, facing page 1481), the difference between the two electrodes is very marked. Fig. C shows the positive electrode. The discharge is in intimate contact with the end of the electrode. Fig. D shows the negative electrode. Although the discharge is taking place in air at normal pressure the dark space intervening between the discharge and the negative glow is plainly visible, and close examination will reveal a second dark space, exceedingly narrow, surrounding the end of the electrode. In view of the fact that the operation of the klydonograph must consist of a minute discharge to the film in air, the difference between the figures obtained for positive and negative surges may perhaps be the consequence of differences in the nature of the discharges similar to those shown in the photographic reproductions.

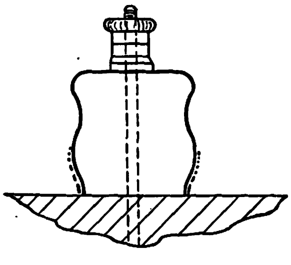

FIG. A.

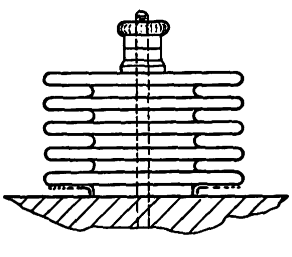

FIG. B.

Mr. G. L. Addenbrooke: My work on this subject, which has been referred to by the authors, is contained in a paper [*] published in 1927. When Lord Armstrong published his fine volume [†] on the subject not much was known beyond the original Lichtenberg figures. He made photographic reproductions of such figures in an improved form and published illustrations of them on a large scale. The work was continued under his auspices by Prof. Stroud and gorgeous effects were produced, but they were practically inexplicable at the time. Sir J. W. Swan published a paper [‡] in 1898 in which, in my opinion, the whole question of these figures was first put on a proper basis. His experiments were carried out with a frictional machine and with points or spheres placed over various compounds of resin and oil. Not only did the resin when charged show figures such as those which have been described, but the surface became indented. Swan was able to keep such charges on a plate of resin for two or three months. I myself have kept a charge for over a month; on heating such charged plates a set of depressions is produced which show as an image of the original charge. My own paper, mentioned above, describes in detail what occurs and shows that the whole effect is due to ionization. If the distance between the electrodes is increased a beautiful effect, which was shown at the Physical Society's Exhibition two years ago, is produced. A large number of impacts take place, as of particles of dust thrown down on the dielectric surface. These particles indent the film and usually have two or three little points running out of them. If a sufficiently viscous dielectric is used it is possible actually to see these charges spreading out towards the circumference of the vessel, and at the same time indenting themselves further in. This seems to me to be the most complete visible demonstration of the action of ions in air that has hitherto been discovered. Effects of this kind are very useful in showing surges on lines, and such surges doubtless occur electrically to a large extent. The difference between the positive and negative discharges has been referred to. Since 1927 I have been trying to measure the currents which pass through insulators owing to these electrical discharges. I find that, for the same voltage and distance between the electrode and the plate under the dielectric, great differences exist between the magnitudes of the currents which pass through as their signs are changed. The current is always much larger when the point in air is positive. With the point actually entering the dielectric, I find again that there is a similar difference in the magnitudes of the respective currents, although the ratio may not be quite so large as when the discharge is partly through air. The experiments seem to show that if any point or sharp edge carrying a higher alternating potential than its surroundings is within a dielectric, say a liquid, there will be a tendency to discharge from this and the discharge with an ordinary alternating current will be greater in the positive phase than in the negative phase. The discharge of negative ions is not sufficient to neutralize the discharge of positive ions, so that there exists in the dielectric a small permanent positive ionization which is certain to give rise to chemical action. This, I think, is the cause of sludging in oils, and actions which occur in cables.

Mr. J. J. C. Berkeley (*communicated*): During the early part of January, 1930, strong gales swept over Holland and north-western Germany, and frequent failures of supply occurred. The whole of the Lower Rhine district is supplied with current at 220 kV and 100 kV by the Rheinisch Westfälisches Elektricitätswerk (the R.W.E.). In the daily Press the cause of the failures was attributed to flash-overs due to deposits of salt on the insulators. Rhenish Westphalia is about 180 miles away from the sea coast, and the strings of insulators, of the cap-and-pin type, are from about 4½ ft. to 6 ft. in length for the high voltages employed. In my opinion the deposit was due to the strong winds having carried moist air, saturated with salt, so far inland; on the moisture evaporating, a crust of salt was left on the insulators. This opinion was shared by the R.W.E.

Mr. J. H. C. Brooking (*communicated*): The paper refers to a number of shut-downs, due to salt being deposited on the insulators during storms from the sea, and to the difficulty in recommencing the supply, due to the salt adhering firmly. No cure is given for this trouble, except systematic cleaning of the insulators with scrubbing brushes and water; and the opinion is offered that "something more than over-insulation is necessary." It may, therefore, be useful to mention the experience of the Lothians Power Co., who have found that where their lines, situated right on the sea coast, were fitted with Pernax patent bird guards there was no trouble during the worst salt storm experienced (November, 1927); but that lines fitted with similar insulators, without bird guards, 10 miles from the coast, flashed over several times during that storm. The Lothians Power Co. consider that these guards were entirely responsible for this difference in results, thus serving the double purpose of preventing birds and conductive deposits from damaging the lines and plant.

Dr. J. L. Miller (*communicated*): The klydonograph has been too long neglected in this country, owing, I suppose, to the comparative rarity of severe thunderstorms and, until recent years, the small number of high-voltage overhead lines in operation. In the United States, however, it has been a very valuable instrument in the solution of many of their lightning problems. In the Ferranti Laboratories we have been using several klydonographs for some time, and the experience we have gained may prove of interest. The first thing which impressed me was the small size of the figures, but I presumed this was necessitated by the limiting width of the film. If I am correct in this assumption, I feel that it might have been desirable to use a wider film and work higher up on the calibration curves by altering the potentiometer ratios, as I am of the opinion that the larger figures are always more reliable. At the same time, it must be remembered that the records obtained by the authors show a series of small surges rather than a few high-voltage lightning transients, and, as they point out, a critical analysis, which is often attempted in the latter case, was both impossible and unnecessary. I was glad to see some information regarding the shape of the electrodes, as this appears to have been neglected in the papers previously published. As we usually employ the instrument on artificial surge work, the time element does not enter into the matter, and so we are able to use plates and needle-point electrodes. I note that the authors calibrated their records on a 50-cycle wave, at the same time mentioning that some observers had noted a larger figure with steeper wave-fronts. I should therefore be glad to know whether they have observed any difference between the 50-cycle calibration and, say, a calibration with the wave having a front of 5 micro-seconds. Compared with the former, the latter is a relatively steep wave. Actually, we have found that the 50-cycle calibration is generally slightly smaller than the impulse figure, and that the difference between waves of different wave-front steepness, if it exists at all, is so slight as to be masked by the other inaccuracies of the instrument. It has been suggested that surface leakage across the plate would account for this variation in size with the slower waves. Obviously, with steep-fronted waves which rise to their maximum value in a micro-second or so, surface leakage will be of no importance, whereas with 50-cycle waves it might have some important bearing on the results. Referring to Fig. 6, where the relationship between the radius of the figure and the impressed voltages is given, I find that there is a difference between the authors' calibration and our own. A few typical records obtained in our own laboratory have been collected in Table A, the figures given therein being obtained with the usual simple series impulse circuit with the klydonograph connected across the resistance.

Assuming that the calibration law is a linear one after the critical point is passed, and making the further assumption that both the authors' figures and our own are averages of a large number of experiments, the table gives $E = 5 \cdot 65r$ (approx.), where E is the stress (kilovolts) and r is the radius (cm) of the positive figure. In Fig. 6, at 8 kV the radius of the figure is about 11·8 mm, giving $E = 6 \cdot 78r$, indicating a smaller figure than our own at the same voltage. I feel that this difference is due to calibrating with 50-cycle sine waves, because tests 5 and 6, which were obtained under these conditions, give $E = 6 \cdot 34r$, which is nearer the authors' figure. It might also be stated that the discrepancy is due to a different speed of plate, but test 4 indicates that this is not the solution. It might be added that Magnusson in his paper suggests $E = 5 \cdot 9r$, which is very near our own constant, and a similar agreement is obtained with the records of McEachron and Cox and Legg. With an ordinary Kodak film, figures similar to those obtained with plates were found. It can be seen that agreement between the results is very good, but more erratic figures are to be expected with the lower voltages, and for this reason we prefer to use the larger ones. However, with the latter, records appear to go wrong now and then, and I feel that the authors' figure of ± 10 per cent as the possible error is about right for our own experiments if extreme records are eliminated. Some of the American papers, however, give about 25 per cent as the possible error. In connection with the theory of operation of the klydonograph, I am of the same opinion as the authors when they surmise that the figures are caused by light emitted from the discharge, and we have performed many experiments which tend to confirm their conclusions. For instance, Magnusson obtained a blurred figure by placing an additional glass plate on his photographic plate, and we did the same thing by reversing the photographic plate and placing the electrode on the glass side. We have also attempted to take records under oil, but we failed to obtain a result. Thin films of oil on the plate gave a lighter and more hazy figure, indicating that the discharge took place on the top surface of the oil. We also took records using a colour plate of the type where the screen is combined with the emulsion. With the electrode on the emulsion side, a clear white figure of standard size was obtained. With the electrode on the glass side (so that the light would have to pass through the filter before reaching the emulsion), a blurred light-blue figure was obtained. The plates used, however, from my experience with ordinary colour photography, are liable to take on a blue tinge, and perhaps the blue figure was due to some inherent quality in the plate, but I give the idea for what it is worth. In this connection I should like to know what type of "safe light" was used in the authors' experiments. We have obtained records when the potential has been increased very slowly, and they were much smaller than the average figures. In appearance they were similar to McEachron's, and, as he describes them in his own words, they "consisted of fine straight lines emanating from the centre and perhaps extending only partially round the entire electrode. The appearance is much like that of fine hair being blown out by some force at the centre." Turning to the other aspect of the paper, I feel that the importance of a trip-out due to a lightning stroke hitting a line is rather underrated. The voluminous literature in American journals and the amount of money expended on investigational work rather tend to disprove this.

TABLE A.

Test	Plate speed	Capacity of condenser	Voltage across resistance	Diameter of figure	Type of figure
		μF	kV	cm	
1	H & D 400	0·01	12·2	4·28	Positive
2	H & D 400	0·05	12·2	4·5	Positive
3	H & D 400	0·05	13	4·9	Positive
4	H & D 90	0·05	12·2	4·2	Positive
5	H & D 400	—	13 (50-cycle wave)	4·1	Positive connection
6	H & D 400	—	13 (50-cycle wave)	4·1	Negative connection

Mr. J. E. Taylor (*communicated*): The effect on which the klydonograph relies for the measurement of instantaneous voltages is one to which I have, in the past, given some little attention in connection with apparatus for wireless transmission. The best clue to the causes contributing to the electric brush effects concerned, both on the line insulators and on the photographic film in the instrument, is perhaps afforded rather by a close examination of the Lodge experiment on overflow of Leyden jars than by a consideration of the Lichtenberg figures. In this well-known experiment a highly charged Leyden jar is discharged through a suitable circuit so that a strong brush discharge is set up from the edges of the tinfoil coatings along the surface of the glass. If the insulating surface on the jar is not sufficiently extensive a direct flash-over discharge round its edge will occur each time the ordinary spark-gap discharge takes place. The brushing may also be accentuated and the flash-over precipitated by a slight deposit of moisture on the glass surface. In the past this effect has been attributed to surges in the main discharge circuit producing accumulations of voltage at the coatings of the jar. A little consideration, however, shows that this explanation is hardly tenable. Increased voltage at the coatings must mean either an addition to the energy of the system, since the jar must then be more highly charged than at the start of discharge, or a considerable decrease in the specific inductive capacity of the glass. In any case, surges are ruled out by the first consideration. The second is also ruled out for several reasons, the chief being, perhaps, that the effect is independent of the material of which the dielectric is formed, though some materials may offer better surface conditions for its development than others. The conclusion is that there is no rise of voltage that matters at the coatings. An explanation which I gave some years ago * is that there is a progressive surface ionization resulting from an initial creeping away of the charges along the glass surface when the jar is charged. This is permitted by the normal surface conductivity. The circuit becomes oscillatory on discharge and at the first reversal of charges on the coatings the surface-charges then facilitate the production of a high potential gradient over any intervening surface, and, since this gradient rises above that whch can be sustained by the air, a brush discharge ensues whereby an ionized path over the glass is formed. This not only discharges the glass surface but conveys a full reversed charge. At this stage the brush is of a comparatively minor character. The reversal of the surface charge being now affected and having the same sign as the coating from which it was charged, the brush ceases and the ionization fades out before the next reversal occurs. A similar process is again gone through at each reversal of the main oscillation, but the charge on the glass surface creeps a little more, to a degree depending on its duration, each time it is formed and thus continues to extend further away over the glass surface, the brush following suit. The distance to which the brush will extend will be a function of the surface conductivity so long as that conductivity is not too large to keep the potential gradient below the critical limit of air breakdown. The oscillations over the insulators on a high-tension power line are doubtless initiated by the discharge between the creeping charges on the insulators and the power line. The high-frequency effects thus set up appear to be conveyed to the klydonograph. It is within my experience that wireless receivers in the vicinity are strongly affected when the discharges occur, even without actual " flash-over."

Mr. E. Wilkinson (*communicated*): In connection with the effect of d.c. voltages upon the film in a klydonograph some interesting experiments have been carried out in the University of Liverpool. The authors claim that no figure is obtained by the application of d.c. stresses, but such figures have been recorded and they cannot be explained by the existence of ripple in the output voltage. The result of the experiments supports this opinion, and, moreover, it illustrates how the figures observed by McEachron are formed. A supply of direct current at 10 000 volts was available from a full-wave kenotron rectifier set, the circuit diagram of which is shown in Fig. E. The stress was applied directly to the klydonograph in series with a protective resistance. In the first of two tests a current of 200 mA was passed through the resistance R, the variation in voltage under these conditions being about 0·5 per cent (calculated and measured). A specially constructed klydonograph was used, through which the film could be wound by hand. The voltage was first switched on and the film was moved a few inches while the voltage was maintained. It was then left in this position for 10 minutes, the purpose of this procedure being, of course, to separate the initial surge figure from any figure due to the direct current. A figure was produced under these conditions (see Fig. F on Plate IV, facing page 1481). The radius of the figure is smaller than that of a figure obtained by a surge at the same voltage (the circle in Fig. F shows the size of a positive surge of 9 600 volts). It seemed possible that the figure was caused by the ripple, even though the maximum deviation was only about 50 volts. Another test was performed, therefore, with the valves on open circuit ($R =$ infinity, in Fig. E). The output voltage under these conditions is theoretically perfectly smooth, but a figure of similar shape and magnitude was again obtained. As a final and conclusive test the condenser of the smoothing circuit was charged and the power supply disconnected. The condenser alone was used as the source of stress. In this case also the figures were formed. It seems, therefore, that the effect is due to the total stress and not to the ripple. That the authors did not observe such figures may be due to one of two causes. The voltage employed by them may have been insufficiently high. Secondly, the voltage may not have been applied for a sufficient length of time. The figures definitely take time to form, the actual formation of the d.c. figure being shown in Fig. H (see Plate IV, facing page 1481). In this test a d.c. stress was maintained while the film was moved through the klydonograph [from (*d*) to (*e*), Fig. H]. Streamers will be noticed leaving the zero line. When the film is stationary for a period of time the lines build up into a full figure (at the rate of about 40 lines per sec., in one test). Another interesting result was

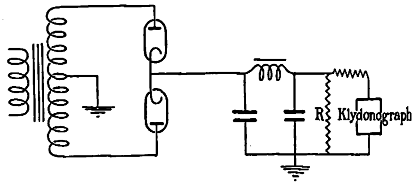

FIG. E.

---

* *Journal I.E.E.*, 1922, vol. 60, p. 853.

noticed. If a steady potential was applied to the klydonograph and this was suddenly raised to a higher value, the size of the figure produced seemed to depend upon the final voltage reached and not upon the rise in voltage. Figs. G and H (see Plate IV) are the results of two experiments which demonstrate this. The klydonograph was connected across a portion of a potentiometer resistance the other portion of which was paralleled by a short-circuiting switch. The film was first calibrated by applying a surge corresponding to the voltages across the klydonograph when the switch was in the open and closed positions respectively. With the switch open, the lower voltage was switched on. The film was moved a short distance and the short-circuiting switch closed, thus increasing the voltage suddenly to the higher value. In the experiment of Fig. G the power was then switched off, while in Fig. H the film was turned through before switching off. The results show fairly definitely that the value of the surge does not control the size of the resultant figure. The size is determined by the final voltage reached.

Messrs. S. W. Melsom, A. N. Arman and **W. Bibby** (*in reply*): We have to thank Mr. Wedmore for his helpful and instructive contribution to the discussion, and especially for suggesting that the Electrical Research Association might proceed to investigate fully the whole question of surge phenomena. In view of electricity supply developments, the large units involved and the extension of overhead-line systems, such an investigation is imperative unless the electricity supply authorities —and subsequently, of course, the consumers—are going to bear the very heavy cost of a large number of breakdowns such as have occurred quite recently on power supply systems where high pressures have been used without adequate knowledge either of manufacture or of operation. It is safe to say that the cost of such a complete investigation would be not more than one-tenth of the cost of making good the breakdowns resulting from the lack of knowledge. From this point of view, it is disappointing that those more particularly interested in transmission-line design, manufacture and operation, have not taken part in the discussion of the paper, but one may hope that they will co-operate when the Research Association formulates its proposals for the research.

Dealing with the questions of detail put by Mr. Wedmore, we did not attempt to work with a higher temperature, but we agree that there are possibilities in this direction. Actually, more recent work carried out on the effect of temperature gave conflicting—or, at least, irregular—results, and a good deal of further work on those lines is probably required. The amount of energy taken by the klydonograph is minute, and, while definite measurements were not made, there seems to be little doubt that any energy loss here does not affect the calibration beyond the limits of error stated.

We are glad to learn from the remarks of Prof. Marchant and others that further investigations are being made into the physical properties of the instrument. Such complete work is needed, but it was hardly possible for us to undertake it all, in view of the importance of obtaining roughly quantitative results so as to clear up difficulties on certain lines. In reply to Prof. Marchant's specific question, we have not done any work with reduced air pressures. The effect of temperature is dealt with in reply to Mr. Wedmore; work on this subject is proceeding and it seems possible that some factor other than film sensitivity is having an effect. The usual type of earth wire suspended from pole to pole and beneath the line conductors was used. The point mentioned about the thickened insulators at both ends of the transformer is interesting corroboration of the view which we have put forward, and Prof. Marchant is to be congratulated on his investigation on the strength of insulating materials under high-frequency discharge. Practically no modern information is available on this subject and Prof. Marchant's results when available should be of the greatest value.

In reply to Mr. Herwald, South Wales has been stressed in the paper, but solely because of a combination of circumstances which led to a great deal of trouble on one particular line. Climatic conditions were undoubtedly responsible for a great deal of the trouble, but such conditions and surges occur on other lines, especially composite ones. Possibly there is a clerical error in Mr. Herwald's results which show the high inductance of the cable section as compared with the overhead line. Actually, the cable has a much lower inductance and much greater capacity than the overhead line; consequently, the tendency will be for the cable to reduce the voltage component of a wave. As mentioned in the paper, however, the cable must be of fair length to effect any appreciable reduction.

We agree with the greater part of Mr. Goodlet's remarks and we have to thank him for the interesting additional information which he adduces. The improved performance claimed for the inverted type of sealing end, however, is mainly due to the fact that with this design the sheds can be correctly arranged in the electric field. We are of opinion that the deep sheds are beneficial in most cases, but we agree with Mr. Goodlet that in some situations they would not greatly improve matters. Regarding the size of the figure with high-frequency oscillations, we did not make definite measurements but relied on the American investigations. It is interesting to note that Dr. Miller states in this discussion that the high-frequency figures are slightly larger than with the usual frequencies of power supply.

Mr. Harris is no doubt correct when he says that most of the insulators on the line were near the flash-over point. This is evident from the amount of discharge on the line. But the fact that flash-over and more intense discharge occurred always on the sealing-end insulators bears out our theory that with the sheds correctly disposed there is less discharge and the insulator does not so readily flash over. In fact, on this particular line, there was not a single instance of flash-over on a sound pin insulator. We are confident as to the accuracy of our statements regarding the increase of the voltage at which discharge commences without a corresponding change in the flash-over voltage. A number of tests on various insulators—some specially made—proved this, and one case may be mentioned of an insulator where the field was altered by the interposition of metal sheds and where the voltage at which discharge commenced under wet and dirty conditions was doubled, while the flash-over voltage was actually reduced by about 20 per cent. As mentioned in the reply to Mr. Goodlet, the success of the inverted type of sealing end was due to the arrangement of the sheds with regard to the field rather than to the depth of the sheds, although it was felt that the latter was an advantage.

In reply to Mr. Riley, it is quite possible that discharge occurring in the interior of a cable may have produced the oscillations shown. In fact, examination of one set of films led us to expect that a breakdown would occur, and this duly took place, but it would be necessary to consider many other features of the circuit before we could say definitely that this was the cause of all the surging. Mr. Riley's results with direct current are interesting—we had not facilities for such high voltages—and it seems probable that with such voltages definite figures can be obtained with direct current.

Mr. Collis raises a number of points, possibly from a rather different angle. First, the oscillograph available did not respond to the very high frequencies; it seems doubtful whether an instrument which does not show the surges actually present—admirable as are its characteristics in other directions—can be considered to have a higher mathematical accuracy than one which does record them, but to a comparatively low order of accuracy. The system was, of course, earthed, as are practically all 33-kV transmission systems. The complete system was so intricate that it was difficult to arrive at even a rough approximation of the impedance and resistance, but we were satisfied by a long series of experiments that there was no question of resonance on the system and especially no possibility of resonance due to the transformers or synchronous motors. Mr. Collis is probably thinking of indoor insulators when he says "it is comparatively easy to design an insulator . . . that will eliminate brush discharge or ionization." It is certainly not an easy problem in the case of outdoor and dirty conditions.

We agree with Mr. Ockenden that leakage along the insulator shown would have a serious effect. The first insulators used were of porcelain and had the shape illustrated, but owing to trouble with leakage they were replaced by ebonite insulators having a special petticoat with a very long leakage path, the two main surfaces being protected by the petticoat. These insulators were completely satisfactory.

We have to thank Mr. Addenbrooke for the further description of his work which bears on this subject.

Mr. Berkeley appears to have had similar experience abroad, and it is of great interest to note that in his case salt was air-borne for a distance of 180 miles.

Mr. Brooking's communication draws attention to the efficacy of shielding and, in this respect, bears out the statements in the paper.

Dr. Miller has given a great deal of additional information which it is not possible to deal with except by way of thanks. On the question of the accuracy obtainable with the wider initial line, we agree that where the highest possible accuracy is required, that is to say in the actual measurement of the voltage, the wider initial line is to be preferred. Where, however, as in our case, the existence of surges under normal line operation, and, in particular, their incidence, are of primary importance it seemed better to use the instrument as a surge detector with the times of occurrence most clearly marked, even although this involved the sacrifice of some accuracy in the determination of the actual voltage. The decision to make use of the critical part of the curve in this way was taken deliberately and we still consider that for that particular type of service it is the better method. The difference found by Dr. Miller in the size of the figure due to wave-front is about what we should have expected after a study of the work done on this subject in America. We were unable to make definite calibration with waves of varying steepness, owing to lack of a cathode-ray oscillograph. Calculation is hardly sufficient for such a purpose. The "safe light" used was a "Wratten."

The points raised by Mr. Wilkinson have been partly dealt with in our reply to the other speakers. The interesting results with direct current confirm those referred to by Mr. Riley. Mr. Wilkinson's contribution draws attention to the large amount of work that is required before the physical properties of this very interesting instrument are properly understood.

THE METERING ARRANGEMENTS FOR THE "GRID" TRANSMISSION SYSTEM IN GREAT BRITAIN.

By C. W. MARSHALL, B.Sc., Member.

(*Lecture delivered before the* METER AND INSTRUMENT SECTION, *2nd May,* 1930.)

SUMMARY.

The lecture reviews briefly the provisions of the 1926 Electricity Act which relate to metering. It describes the system of measurement which has been adopted for the main classes of electricity stations connected to the " grid " system, and mentions the constructional features of the instruments used in the Central Scotland and South-East England electricity schemes which differ from recognized meter engineering practice.

The novel features of the general scheme are the use of summator meters, long-scale maximum-demand indicators, special devices for recording maximum power demands, and reactive-component meters.

Actual instruments were used for demonstration, and slides of typical installations were shown at the lecture.

GENERAL METERING REQUIREMENTS.

The provisions of the Electricity (Supply) Act, 1926, which specifically relate to the subject of metering are summarized here, as they form the basis of the measuring arrangements which have been adopted by the Central Electricity Board for the " grid " system.

FIG. 1.—Metering scheme for stations without generating plant.

Under the Act, the price at which the Central Electricity Board can supply the owners of a selected station will, unless otherwise agreed, be

(*a*) The cost of production, ascertained in the manner prescribed in Sub-section (3) of Section (7) of the Act, adjusted according to the load factor and power factor of the supply given to the owners of the selected station; together with a proper proportion of the Board's expenses, other than those incurred by the Board in the purchase or generation of electricity; or

(*b*) According to the Board's tariff.

Kilowatt-hours, kilowatts of maximum demand, and power factor are elements which enter into the determination of cost of supply in both cases. The same units of measurement will enter into the Board's tariffs in most cases of supplies to non-selected stations.

Measurement of kilowatt-hours, kilowatts of maximum demand, and power factor of individual circuits had previously been developed to a high standard of accuracy and reliability. The problems introduced by the Act therefore related principally to extension of existing methods to multiple circuits, together with obtaining accuracy of measurement commensurate with the importance of the supplies, as far as is commercially practicable.

The general methods of measurement which have been adopted will first be described, and then particular examples of typical equipments will be illustrated and demonstrated.

Stations to be connected to the grid system may be divided into two main types:—

(i) Those in which there will be no generating plant in operation.

(ii) Those in which there will be generating plant in operation.

The equipments provided in the two cases are illustrated diagrammatically in Figs. 1 and 2 respectively.

Fig. 2.—Metering scheme for stations with generating plant.

Fig. 1 shows that each incoming circuit from the grid system is equipped with a kWh meter and a reactive kVAh meter, the purpose of the latter types being to determine, in conjunction with the energy meters, the power factor. There are, in addition, summator meters for determining the total energy input and the maximum power demand, and the corresponding reactive quantities.

The equipment for a station in which generating plant will be in operation is shown in Fig. 2, and is as follows. There are input and output kWh meters and reactive kVAh meters in each connection between the grid and the undertaking, and an output kWh meter and reactive kVAh meter in each generator circuit. Summator meters are provided to give the total energy and maximum power demand and the corresponding reactive quantities of (*a*) the import from the Board, (*b*) the output from the generators, and (*c*) the supplies to the undertaking for its own requirements. The energy supplies to the station auxiliaries are also measured, but the reactive quantities and maximum demands relating to the auxiliary supplies are, in general, estimated. The supply to the undertaking for its own purposes is the sum of the corresponding imported and generated quantities, minus the sum of the quantities exported and used for auxiliary purposes. Check equipments are provided on main circuits for energy measurements. There are no check reactive-component meters. The summators are verified by comparison between their registrations and those of the component meters (termed summating meters).

These are very briefly the general provisions which are made for measurement. The classes of instruments used are, kWh meters, reactive kVAh meters, summator meters and maximum-demand indicators and recorders. The term "recorder" is used in its most general sense and includes printometers and graphic meters.

The instruments which are being used on the Central

Scotland and South-East England Schemes will now be described, the schemes being considered in chronological order.

The kWh meters used in the Central Scotland scheme are of the Metropolitan-Vickers N.A. type. The new or unusual constructional features of this instrument are as follows. The voltage and current magnetic circuits of the electromagnets form an almost entirely closed circuit, so that flux leakage is negligible. There are four permanent brake-magnets, thus ensuring that the probability of large changes of accuracy due to change in braking flux is reduced relatively to that of most commercial models of energy meter. There is partial correction for changes in accuracy due to temperature-changes. A device used for transmitting impulses to summators is fitted to all main-circuit meters and takes the form of a 3-segment commutator mounted on an auxiliary spindle driven from the main spindle of the meter. The reactive-component meter is identical in general construction with the energy meter. The windings of the potential coils are different, however, a series non-inductive resistance being used in conjunction with each element. The object of this is to cause the potential flux to lag 60° behind the applied voltage, instead of 90°, as in the case of the normal energy meter.

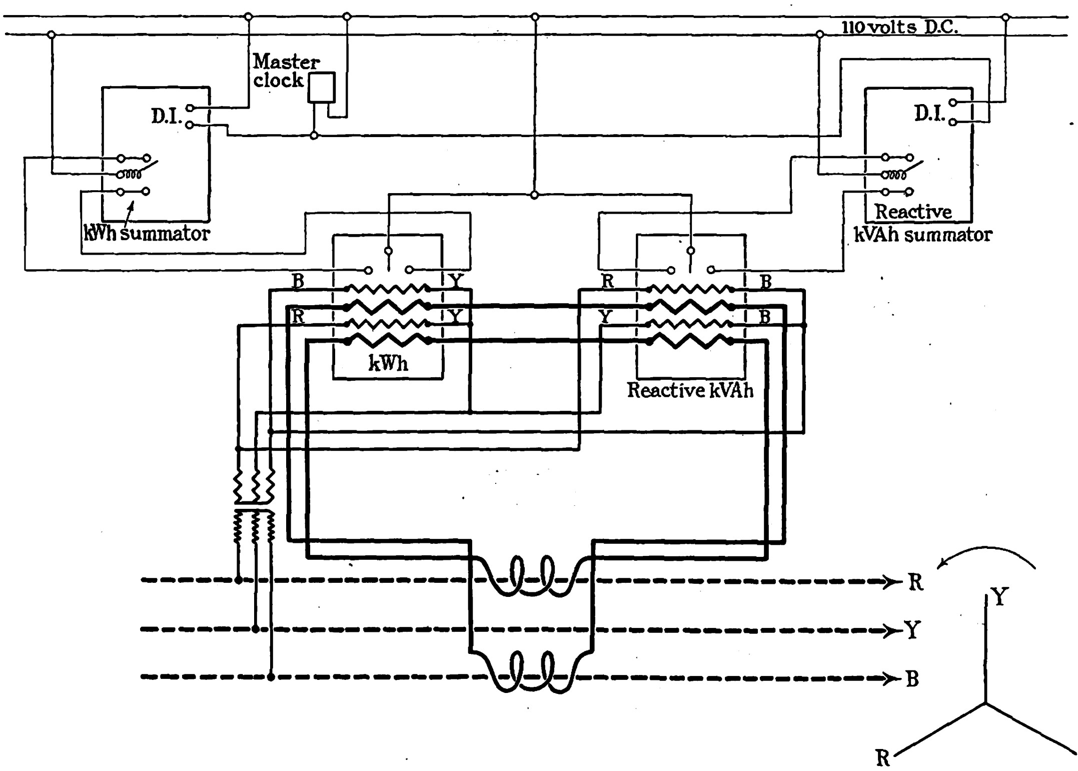

FIG. 3.—Diagram of connections of kWh and reactive kVAh meters on the Central Scotland Electricity Scheme.

Fig. 3 shows the general diagram of connections of the energy and reactive-component meters used in Central Scotland. It also shows diagrammatically the connections between these meters and their associated summators.

Vector diagrams showing the phase relationships between voltage, current, and flux for each element of an energy meter and of a reactive-component meter are shown in Fig. 4, together with the contributions of the separate elements to the total torque. The net result is that the total torque in the energy meter is proportional to cos ϕ, while in the reactive-component meter it is proportional to sin ϕ.

SUMMATORS.

Impulse summators are used in all cases in the Central Scotland scheme. The general principle on which these instruments operate is as follows. Each summating meter in a group of which the resultant is required is provided with a contact-making device, by means of which the circuit between a source of energy and a receiving circuit in the summator is closed. By this means current impulses are transmitted from the summating meter to the summator at definite energy intervals, as registered by the summating meter. The source of energy for supplying the impulses is a storage battery, and the contact-making device is the commutator previously mentioned in the description of the summating meters. The receiving element in the summator meter is a solenoid electromagnet, which actuates a ratchet and pawl for registering the number of impulses passing through the solenoid circuit. Each summator receiving element has a standard meter dial attached to it, but this is for convenience in checking the components and is not an essential feature from a theoretical standpoint.

Fig. 5 shows diagrammatically how the registrations of two elements of a summator are combined to give their resultant. The scheme employed is to couple the driving shafts of the two elements through a differential gear. This principle can be extended to any desired extent, but in practice it is found to become somewhat cumbersome if the number of elements exceeds 12. The chief objective aimed at in the summator meter is the maximum demand. This is obtained by fitting maximum indicators of the Merz type on the " resultant " section of the instrument. In view of the extreme importance of the maximum-demand measurements, accurate and definite readings are essential. Permanent records of the readings are likewise wanted for operating as well as for accountancy purposes.

FIG. 4.—Vector diagrams of energy and reactive-component meters on the Central Scotland Electricity Scheme.
Resistance is inserted in series with each voltage coil to allow the voltage flux to lag behind the current by only 60°.

The indicator part gives an exceptionally long scale, due to the use of the device shown in Fig. 6. This was invented by Mr. O. Howarth, of the Lancashire Electric Power Co., and was developed by the Metropolitan-Vickers Electrical Co. Gravity resetting is used to overcome the difficulties encountered when spiral springs are employed through very large angles. A record of each maximum demand is printed every half-hour. The printometer attachment prints four significant figures definitely and a fifth figure can be read accurately from a side scale.

SOUTH-EAST ENGLAND SCHEME.

The energy meters for the South-East England electricity scheme are of the Ferranti F.G.L. type and have also many interesting and novel features. There are two driving elements per disc and these are so placed that side-thrust on the bearings is eliminated, with the result that the spindle has no tendency to move from the centre of the jewel. About 80 per cent of the weight of the rotor is borne by permanent-magnet suspension, so as to relieve the bottom jewel of excessive mechanical stress. Eight permanent magnets are provided for each meter. The object of these features of design is to ensure that the life of the meter will be long even in comparison with that of normal induction kWh meters, which are already very satisfactory in this respect. The reactive-component meters for this scheme are identical with the energy meters. In this case the potential to the reactive-component meter is supplied through a quadrature transformer.

The general diagram of connections of the energy and reactive-component meters for one circuit is shown in Fig. 7, and a vector diagram illustrating the principle of the quadrature transformer is shown in Fig. 8.

It will be recognized that this scheme for measuring the reactive component, although involving the use of

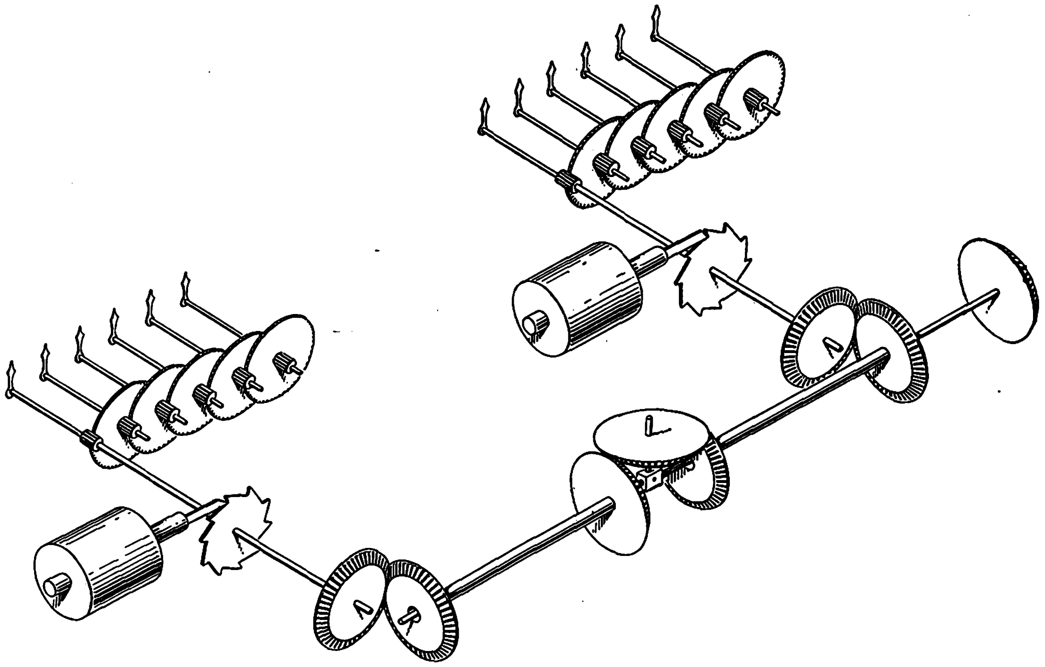

FIG. 5.—Mechanical addition of registrations (diagrammatic).

an additional piece of apparatus and increased volt-ampere consumption, has advantages in regard to standardization of material and calibration methods. The contactor attachment, which is used for summating purposes, is a cam-operated 2-way switch.

In the summators, mechanical addition by means of differential-gear couplings is used, and the scheme does not differ materially from that previously described. There are, however, numerous interesting differences of detail in connection with the types of impulsing electromagnet, and the arrangement and type of differential, for example.

The long scale of the maximum-demand indicator has been obtained by direct gearing-up, but the disadvantages of high driving torque and excessive backlash usually associated with this arrangement have been eliminated by fitting spiral-spring control to both gear elements. The energy required for driving the higher gear is then derived from resetting, which is done by hand.

The maximum-demand printer is a separate element. A motor-driven chart is used, and carbon type printing, similar to that employed in typewriters, has been adopted in preference to ink printing. General information regarding the performance of meters and current transformers is given in an Appendix.

APPENDIX.

GUARANTEED PERFORMANCES OF METERING EQUIPMENTS.

The guaranteed accuracies of the energy and reactive kVAh meters are indicated in Table 1, which shows the maximum errors under different loading conditions.

The conditions are made somewhat less difficult for meters on generator circuits, so as to allow lower-grade—and consequently cheaper—current transformers to be used. This is justifiable because of the fact that the generator circuits work on much higher average loads than the other circuits. The actual accuracy obtainable on the generator meters will therefore be at least as high as on the others. The current-transformer accuracies

also vary with the loading conditions of the circuits on which the transformers are used. Those in generator circuits are British Standard class A, while those in auxiliary circuits are class B, both classes being those given in B.S.S. No. 81 for instrument transformers.

The Board's circuits carry loads which vary between wide limits and which may have low power factors. For this reason it was imperative to give the meter manufacturers every assistance by providing highly accurate current transformers. The accuracies which transformer manufacturers have been able to guarantee are shown in Table 2.

The potential transformers are of grade B, to B.S.S. No. 81. The guaranteed maximum temperature-coefficient of the meters, both for kWh and reactive-kVAh measurements, is 0·1 per cent per degree C. The guaranteed maximum error in transmission between summating and summator meters is 0·1 per cent.

Discussion before the Meter and Instrument Section, 2nd May, 1930.

Mr. T. G. N. Haldane: I think that in many respects the equipment which has been adopted by the Central Electricity Board is likely to be a standard for the whole country in the future. The author's task has been a difficult one, because it is inevitable that the Board's metering equipment should be essentially complex. I should like to deal with a few points in connection with it for the sake of those who are not, perhaps, very familiar with the provisions of the 1926 Act and the reasons why the somewhat elaborate equipment is necessary. As the author has explained, the three essential quantities to be metered are, first, the total units and the maximum demand from the generators; secondly, the total units and the maximum demand imported from the "grid" through the Board's transformers; and thirdly, it is necessary for the purpose of the Act to arrive at the total units and the maximum demand supplied to the undertaker for his own purposes from the station. It is this third quantity which has led, I think, to the more serious complications in the metering equipment. When the matter was first being considered two methods were available for dealing with this point. First it was possible to put integrating meters on each feeder going out from the station and to sum these and thus obtain the total demand. The other method, and that which has actually been adopted after careful consideration, is to add together the readings of the generator summator and the "grid" import summator and to subtract from the sum the amount exported to the "grid" system, the total necessarily giving the balance which goes to the undertaker for his own purposes. This method was adopted because the first alternative would have involved a larger number of integrating meters and, furthermore, every time any feeder was altered in the station an alteration in the Board's equipment might have been required. Of the various new features in the equipment, I think that the use of impulse summation is possibly the most striking and in some ways the most novel. When the problem was first considered meetings were held with all the meter manufacturers. The various methods of summation were all considered very carefully, and the conclusion arrived at was that the impulse method was the only practical way of dealing with the rather complicated problem of the selected station, i.e. the station where there is generating plant. The impulse summation method was therefore adopted and developed; the panels and summators exhibited by the author are the result. Whereas this method of impulse summation is adopted in the complicated case of the selected station with generating plant, at non-selected stations where there is no generating plant other methods have been adopted. In certain cases current transformers in parallel or multi-element meters are used. Although these methods are simpler they cannot be applied to the complex case of the selected station. I should like to mention that the use of demand recording equipment was not, strictly speaking, essential for the Board's purposes, as by means of Merz type maximum-demand indicators it would have been possible to measure all the quantities necessary for accountancy purposes and required by the 1926 Act. It was felt, however, that the Board's metering equipment had more than one purpose to serve. Primarily it has to measure the quantities required for accountancy purposes, but it will doubtless supply also much information which will be of great value from the point of view of operation. The charts for recording the maximum demand in every half-hour of the day will provide information never before available about the whole supply to the country. For instance, they will allow the diversity of load between different areas in the country to be fairly easily determined with reasonable accuracy. After the points that I have mentioned, and various others, had been settled, a whole host of details remained to be dealt with. Some of these were concerned with the technical construction of the meters—these naturally interested in particular the meter manufacturers—whilst others dealt with the question of whether the proposed equipment would really give the quantities that were required. I think that all these problems have now been solved, and although they were of a very intricate character the outcome has been the production of a fine type of metering equipment. The manufacturers are, I think, to be congratulated on the results.

Mr. O. Howarth: A consideration of the "grid" metering from the supply undertaking's point of view leads one to realize the great importance of accuracy in the measurement of the quantities required. I am glad to see that temperature compensation has been provided, as in this way a little extra accuracy has been gained. The importance of accuracy in the demand-indicator measurement can best be realized, perhaps, by taking an actual case which may occur in the future. I have in mind a station where the generating plant may be dealing with a load of about 62 000 kW and the local load may be of the same order—66 000 kW for instance; thus 4 000 kW will be imported from the "grid." This amount will presumably be measured on the import meter shown in the diagram of metering equipment for selected station with local load, but the maximum import load for which this will have to be arranged is of the order of 60 000 kW, so that the 4 000 kW will be measured by an instrument reading up to 15 times the actual load which it is then measuring. Thus the kW purchased at "grid" price will be purchased at one-fifteenth of the full-scale reading. As the demand on the "grid" at the time when the undertaking's maximum demand occurs may not be the actual maximum demand imported, this reading may have to be taken (for charging purposes) from the chart. Assuming a price of £3 per kW, 4 000 kW represents £12 000 per annum and an error of 1 per cent in this represents £120 per annum, so that it is obviously quite worth while to spend a little extra money on metering in order to cut down this possible 1 per cent. Further, the reading for several months may depend on that of one particular month. The measurement of the reactive kVA is also connected with this question. Where the generating station is supplying a load almost, but not quite, equal to the undertaking's load, the balance of load may be imported from the "grid" or exported to the "grid" at a leading power factor without disturbance of the usual operating conditions on the system. A possible case is that in which this small extra load is being imported from the "grid" at a low leading power factor. Assuming that non-reverse stops are put on the reactive meters, the import summators will register this load as having unity power factor, whilst the undertaking's load and the station load will be measured at their correct power factors. Will the undertaker pay for the imported load at the "grid" rate, unity power factor? Considering the case where the generating station is producing rather more current than is required locally, the time of maximum load is the critical period and at maximum load a little may be exported at a leading power factor. The local and station loads will again be correctly registered, but the import reactive summator will also register. Will this registration be ignored in the charge? It seems to me that rather a large sum of money is being spent in order to measure the power factor, because I feel that operating conditions are such that the power factor at times of maximum load is apt to be an arbitrary quantity. In the case of selected stations, where conditions of loading are fairly steady, the variation from one month to another of conditions just at the time of maximum load will perhaps be so great that the Board and the undertaking may come to terms as to what is the power factor at the selected station and of the undertaking's load. We can hardly expect the Board to get these rather complex metering arrangements into satisfactory operation without encountering difficulties. I think that the British manufacturers who have gone out of their way to develop this metering equipment are to be congratulated; it would have been a great pity if, having established our grid, we had had to go abroad to buy suitable metering equipment. British meter manufacturers have not only developed the step-by-step summation gear, but in addition they have increased the accuracy of their ordinary designs of meters, which were already very accurate.

Lieut.-Col. K. Edgcumbe: I should like to hear rather more about the current transformers used with the Board's testing equipment. In general, I hardly think that engineers, when specifying current transformers, pay sufficient attention to the value of the secondary burden. In many cases a burden as high as 40 VA is called for, whereas the demand made by the integrating meters and their connecting leads would not, I imagine, exceed 10 or 15 VA. With "wound" current transformers this question is of minor importance, since such transformers can be designed for 1 000 or 1 500 ampere-turns, but with bar-type current transformers (which are now so popular for e.h.t. circuits) the ampere-turns are definitely limited to the full-load current of the line. This may amount to 200 amperes or even less, and to give reasonable accuracy at a burden of 40 VA with only 200 ampere-turns is quite impossible. For this reason, every item of the burden should be carefully scrutinized and the total, including that of the connecting leads, reduced to an absolute minimum. In some cases, in addition to the integrating meters, it may be desired to operate indicating meters, or even protective relays, from the same current transformers. In that event it will prove far more economical and satisfactory to employ two, or even three, separate cores, mounted upon a single bushing, each core being designed for the particular burden and degree of accuracy demanded by the gear which it is to operate. The cost of an e.h.t. current transformer depends so largely upon that of the insulator that the provision of two or more cores adds but little to the cost. Another matter which I should like to emphasize is the importance of reducing the external diameter of the bushing to the lowest possible figure, consistent of course with adequate electrical properties. The accuracy of a current transformer is very adversely affected by any increase in the length of the magnetic path. The author mentioned the necessity for a clock to operate the maximum-demand indicators of the meters. Although he did not describe it, I believe that he uses an impulse master clock. Has it occurred to him to use this same master clock for controlling the frequency? There is no doubt, I think, that in a short time every power station will have to use a standard clock for frequency control. It is now becoming impossible to leave frequency to look after itself; it has to be kept accurately constant, more especially when stations are interconnected. If a master clock is already available for the maximum-demand indicators, it can either be used to drive the frequency-controlling meter, as is now being done by the London Power Co., or, if once the frequency has been controlled, that frequency can be used for driving synchronous motors in each of the maximum-demand indicators, thus ensuring that they are all in step and all accurate as to timing. This is already being done in several stations.

Mr. G. A. Cheetham: In order to appreciate the problems of inertia, mass, etc., with which we have been dealing, it must be realized that each of the impulse elements probably makes about 2½ million impulses per year. As a previous speaker has said, the results prove that if problems are given to British engineers they can satisfactorily solve them without going abroad.

Mr. Wilfred Holmes: Regarding the current transformers which are being used for the grid, I should like to say that I am quite satisfied that their capacity and accuracy have been thoroughly investigated. The meter engineers were asked to get a certain accuracy and in order to obtain it they had to demand a certain accuracy in the current transformers. Thus the precision transformer as required for the grid was produced. I should like to know the author's opinion regarding the testing of meters operated from transformers. I find that first to test the transformers, then the meter, and finally to combine the two curves is a method which gives the best results. There is great difficulty in obtaining a large-current standard wattmeter reasonably accurate and robust enough for commercial use, while a 5-ampere standard wattmeter is very satisfactory. There are now many methods of measuring accurately the ratio and phase-angle error of the current transformers, and accurate methods of testing such transformers have been described in the *Journal.*

Mr. C. G. Mayo: I agree with Colonel Edgcumbe that with bar-primary current transformers for small primary currents it is extremely important to keep the burden to a minimum; in fact, below certain values of primary current the costs and dimensions become quite excessive if the burden is of the order of 40 VA, and I think that, generally speaking, this magnitude of burden is not realized. Another point raised by Colonel Edgcumbe is that all the burden does not require the same accuracy, and a very great economy could be obtained, as he suggests, by splitting up the burden and supplying it from two separate cores. With regard to the quadrature transformer on the South-Eastern metering, it is not clear whether this is what is usually called a quadrature transformer, i.e. a reactance with two windings, or a transformer supplied from different phases in such a way that the phase displacement required is obtained between the phases without shunt impedance. If the quadrature transformer takes the form of a reactance with two windings it will be slightly more complicated, but will not differ materially from the other arrangement. If the quadrature transformer obtains its phase displacement without the use of shunt reactance, will it in all cases give precisely correct results, i.e. will the voltage obtained depend only on the voltage upon which it *should* depend?

Mr. S. B. Jackson: Colonel Edgcumbe has raised an important point regarding the frequency control of the system, and I think that everyone recognizes the absolute necessity for controlling frequency within such limits as he suggests, by means of the Warren type of apparatus. It is well known that the obligations which the Act imposes are such that it is impossible to escape from considerations of frequency, but I should like to ask the author what would be the effect of different frequency upon a current transformer and its meter indications. What percentage error would exist at 49 and 51 cycles respectively? Closely associated with this is Colonel Edgcumbe's suggestion that the drive of these instruments should be controlled by synchronous motors. I recognize the great accuracy of the Warren type of control, but it nevertheless has an error due to system frequency variation, and in view of the use of the synchronous clock in driving these instruments and the fact that such equipment permits of a much finer reading than the Warren type of apparatus I suggest that we should not complicate matters any further by introducing frequency drive through a motor from the main system. I should like to refer next to the position of the manufacturer. The case with which the manufacturers were presented had for long been felt to be desirable in the industry, and I am sure that the Act was regarded as a welcome opportunity for the industry generally, because up to the present time there has been no proper method of controlling the meter readings. The necessity for accurate meter readings or for accuracy in general was, I think, admirably expressed when Kelvin remarked "If you want to know anything you must know how to measure." Information of great value, such as system diversity, is obtainable by the use of such instruments. If the electrical industry wants to know anything at all, it must not rely upon the inaccuracies of the human element but it must seriously apply itself to the problems presented to it. It is surprising that the manufacturers waited for the Act before taking advantage of the opportunity which presented itself.

Mr. C. W. Marshall (*in reply*): The discussion has revealed the points of view of practically all classes of engineers who are interested in the operation of the 1926 Electricity Act, these classes being consultants, electricity supply authorities, manufacturers of instrument transformers and meters, and operating engineers.

Mr. Haldane outlines the reasons for adopting the general metering system which is being used. His contribution is complete and calls for little comment. It is authoritative, as he has been in touch with both manufacturers and users of meters since the commencement of the "grid" system. It should be noted, however, that there are additional objections to feeder metering besides those mentioned by him. The loads on feeders are extremely variable and it is difficult to measure them accurately during the light-load periods. Interconnectors introduce further difficulties due to varying power factor, and, finally, extensions to systems are more difficult to take into account than with the arrangement adopted. He has perhaps overstressed the novelty of impulse summation. Twenty years ago, at least, the oscillating meter of the A.E.G. included some of the most important elements of the summation system and was a beautifully developed instrument.. With regard to the use of parallel current transformers and multi-element meters for simple cases of summation metering, these systems will be used when applicable and advisable, and it should be noted that the possibility of simple mechanical summation is not excluded.

Mr. Howarth illustrates the extreme importance of obtaining high accuracy because of the large amounts of money directly involved. It was precisely this circumstance which led to the exacting meter specifications which have been used. The reactive kVA metering equipment in selected stations has been installed primarily to obtain the power factors of the undertaking's loads and of the load on the associated generating stations. I agree that when these loads are approximately equal, accurate metering becomes very difficult. In practice it is impossible to obtain high accuracy at much below 10 per cent of full load, even with energy meters. With reactive-component measurements the difficulties are accentuated. No better method of making the necessary measurements than has been adopted was known to the Board's engineers or their consultants, nor has any better method been suggested in the various conferences which have taken place with engineers of authorized undertakings or meter manufacturers. I also contend that the equipment cannot be simplified if the requirements of the 1926 Act are to be fulfilled. There are, however, circumstances in which it is advisable to come to special agreements on power-factor charges, and a number of such agreements have already been made.

Col. Edgcumbe considers the subject of current-transformer loading in great detail. He can be assured that care has been taken to ensure that the specified loadings for the current transformers required by the Board are not arbitrarily fixed. The actual loadings in a particular case examined to test this point were:—

3 Integrating meters	9 VA
2 Indicating meters	3 VA
1 Telemetering equipment and connecting leads	7·8 VA
Total	19·8 VA

The transformers specified are the nearest British Standard to those required by the loading conditions. The suggestion that multi-core current transformers should be used is a good one, but it introduces the disadvantage of additional pilot-cable cores. System-frequency control clocks appear likely to come into general use and it would be readily possible to adapt them so as to work maximum-demand indicator resetting devices and printometers or recorders. It was considered, however, that the metering equipment was of sufficient importance to justify the use of separate clocks.

Mr. Cheetham draws attention to the mechanical problems involved in the production of the summation equipments. I recognize the fact that this lecture by no means does justice to the detailed design of the instruments involved, and hope that one or more of the designers responsible for these will devote a paper to the subject.

Mr. Holmes introduces the very controversial subject of calibration methods. I, personally, favour his own method whereby meters and current transformers are calibrated separately. The last occasion on which this subject was exhaustively reviewed before the Institution was in 1911, when Messrs. Ratcliff and Moore read their paper * on " Electricity Meters, with Notes on Meter Testing." At that time they showed conclusively that collective calibration of meters and their associated transformers was advisable. The situation has in the interim materially altered. Current transformers have become instruments of extreme precision and their characteristics can be measured accurately and conveniently. The performance of energy meters has also been improved. The convenience of low-current standard wattmeters and of modern current-transformer testing instruments, in conjunction with the above-mentioned improvements in meters and transformers, seems to me to provide sufficient justification for giving separate calibration a definite legal status. Further, the impracticability of testing the complete equipment of meter, current and potential transformers is in itself a justification at least for re-examining the situation.

Mr. Mayo endorses Col. Edgcumbe's opinion regarding the importance of loading in deciding the dimensions and cost of bar-primary current transformers. He also asks for information regarding the construction of the quadrature transformer employed in conjunction with energy meters used for reactive-component measurements. This device is illustrated in Fig. 8.

The information for which Mr. Jackson asks, regarding the effect of frequency variations on meter performance, is dealt with in the Appendix. He is not quite fair to the manufacturers of meters when he expresses surprise that they waited for the 1926 Act before applying themselves to the problems of large-power metering. The Fawssett precision energy meter has long been recognized as an instrument of extreme accuracy and constancy of calibration, and the long-scale maximum-demand indicator had been at least partially developed by the Metropolitan-Vickers Co. before the 1926 Act came into being. Summation equipments have been made by several manufacturers, notably the Aron Co. and Messrs. Landis and Gyr, for many years.

A FEW NOTES ON THE DESIGN, CONSTRUCTION AND MAINTENANCE OF RAILWAY ELECTRICAL SIGNALLING APPARATUS.*

By H. C. TOWERS, Associate Member.

(*Paper received* 17*th October*, 1929.)

SUMMARY.

Although several books and many papers have been written on the subject of railway electrical signalling, it is thought that the following notes may be of interest, as they are intended to bring up points not usually mentioned.

With regard to the remarks on track circuits, the author has recently heard of a new type of impedance bond track circuit employing condensers at each end of the track. It would be interesting to obtain a description and criticism of this type of track circuit.

It is not intended in this paper to deal at all fully with any one of the three branches mentioned in its title, since to do so would necessitate something of the nature of a complete treatise. The object is to deal critically with the main features of each branch and to compare one method with another.

It is assumed that those who will peruse this paper are well versed in the science of railway signal engineering, and are familiar with the usual methods of employing electrical power to further its application. This being understood it will be known that the railway signal engineer has to deal with both the mechanical and electrical side and with other subjects as well. As it is intended to deal with the electrical side only, the main examples chosen will be applicable to main-line suburban systems, rapid-transit lines and the electrical interlocking of large and important yards.

During the last few years traffic on our suburban systems, both at home and abroad, has grown to an enormous extent, and with it has come the necessity for the signalling department to assist in coping with the problems that have arisen. Mechanical installations are perfectly sound and efficient where traffic is light, but where it is heavy it is necessary to employ electricity to assist the signal engineer in his problems. The method of employment will vary with the conditions and will be discussed later.

In all railway signalling departments the one ideal to aim for is standardization of equipment. From a broad point of view equipment may be taken as representing not only individual parts of apparatus, but the principles of the administration as a whole.

In the author's opinion the signalling drawing office should be in the charge of a man who has had practical and theoretical experience in railway signal engineering and who can appreciate the difficulties of the work on the track whilst he is deciding problems in the drawing office. If he has had this practical experience he will aim at standardization of parts and their improvement so that the efficiency of the system as a whole will improve. The designs should be carefully thought out, not only with regard to their efficiency electrically or mechanically but also taking into consideration their accessibility from a practical point of view and the ease with which they may be installed.

It is of great assistance if all such parts, when designed and manufactured, are stamped with a type number or with their respective drawing number. It is then possible to refer to them with precision either in correspondence or when ordering materials.

Another product of the signal engineer's drawing office is the wiring diagram. A wiring diagram for any phase of railway signalling is totally different from the usual type of diagram which is used for general purposes. It therefore deserves special consideration. The designer of circuits for an installation should not only know the general principles of interlocking and that a return is necessary for a feed, but he should be fully alive to the fact that his diagram will be the guide for the signal wireman or installer and that usually this man will, if possible, put his wires where the diagram tells him to. The draughtsman should realize the limitations of one relay or terminal, as far as the accommodation of wires is concerned, and also that only a certain number of wires will go through one hole. If it so happens that the diagram is impossible to follow practically the wiring outside will be altered to suit the conditions and the diagram will no longer be a true record. This is the worst possible thing that can happen, since in complicated electrical interlockings it is absolutely necessary to follow the wiring diagram. If a lineman is out on a signal failure and he finds that his diagram shows three wires on a terminal whereas there are actually only two, he is apt to become confused, particularly if that section is strange to him. During this time trains are being delayed. It is therefore absolutely essential that the wiring on the apparatus should agree with that shown on the diagram.

This points to the fact that the signal draughtsman should be a man with considerable experience in electrical and mechanical railway signalling and with a technical education.

Signal engineers should give their staff the opportunity of being trained in every branch of the work, and it is a great advantage if a signal school is formed. Lectures followed by practical demonstrations will further the usefulness of the artisan staff, and will also enable the administration to learn the progress of apprentices. From the results of a term's work and examination it will be possible to select candidates for vacancies in the department as they occur.

---

* Thesis accepted in lieu of the Graduateship Examination.

Railway signal engineers adopt various methods of making their wiring diagrams for railways, and although in the main their principles agree they are often different in details. A general discussion might enable a decision to be reached as to the best type of diagram to employ.

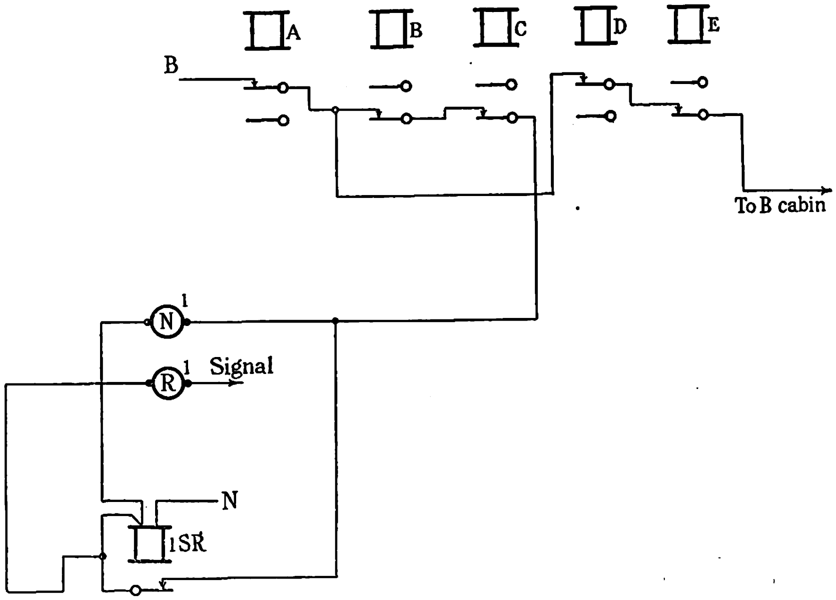

FIG. 1.

Fig. 1 shows a type of diagram which is now obsolete on many railways. The author believes, however, that there are still many that continue to use it. It is only a portion of a complete wiring diagram for track circuit interlocking, set out for discussion. It will be observed that the several branch circuits are shown tapped off other wires in the centre. It can only be assumed in this case that somewhere between two points a wire is joined on, soldered and probably taped. This is, of course, ridiculous. The linesman into whose hands this type of diagram falls has to go first to one end of the line and then to the other to find out which terminal holds the wire belonging to the branch circuit. This type of diagram may save the draughtsman drawing a few additional lines, but it certainly will not enable the original circuit to be traced. A branch circuit should be shown tapped from its correct place. This method, which in the author's opinion is the only one permissible, is shown in Fig. 2.

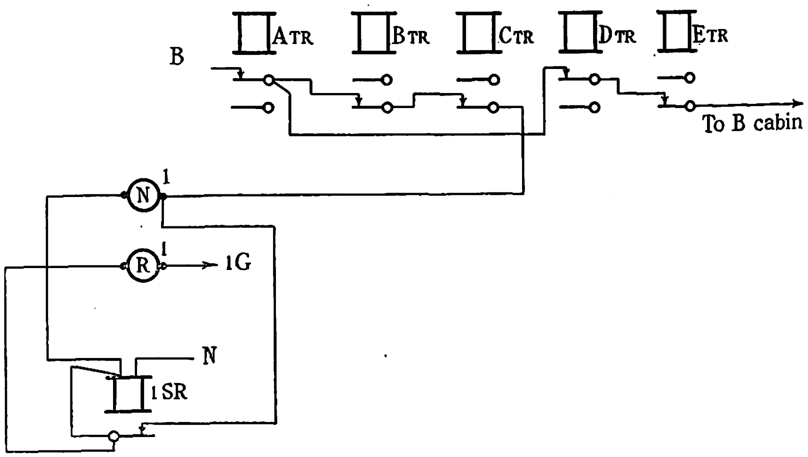

FIG. 2.

In connection with wiring diagrams it is necessary to mention the use of symbols. Symbols are used by power railway signal engineers to label the wires, relays, fuses, etc., on their diagrams. They standardize at once the general terms used and obviate the necessity of lengthy explanation. On most railways to-day which employ power signalling, symbols are used which originate from a signalling association. It is not intended in this paper to discuss their merits. It is only intended to point out that symbols of any form are an advantage and are extremely useful for reference. A standard system is certainly a step in the right direction, since it ensures that any man going from one line to another, as is frequently the case, will not be confused. When one considers that in a large power installation there are perhaps 500 fuses in the basement of the signal cabin, it must be obvious that some system of labelling is necessary. The available space is usually small and will not permit of lengthy explanation, which in some circuits would be necessary were it not for the symbols which are engraved on a suitable label and fixed beneath the fuse base or terminal. To those who may not be familiar with this method the Table on this page will show what is actually meant by a symbol. In addition to the numerical or alphabetical symbols graphical symbols should also be employed so that on wiring diagrams a particular kind of relay, lock or other apparatus may be readily recognized. Many types of relays and locks are used on an electrical interlocking and it is necessary to differentiate between them. In the earlier days it used to be the practice to draw contacts on wiring diagrams, with the object of representing the purpose of such contacts. It is still necessary to do so to-day, but owing to the many varied positions in which one unit may open one circuit and close another such a system would be very difficult to follow and would also be extremely

TABLE.

Letter symbols for wiring diagrams, fuses, relays, etc.

FIRST LETTER.		SECOND LETTER.	
A.		A.	Armature of relay
B.		B.	Back of bottom contact
C.	Control	C.	Point valve
D.	Distant	D.	Distant
F.		F.	Front or top contact
G.	Signal	G.	Signal-operating mechanism
H.	Home	H.	Home
J.		J.	Ground lock
K.	Indicating (visually)	K.	Indicator (visual)
L.	Locking	L.	Lock preventing initial movement of lever from normal or reverse
M.		M.	Lock preventing final or indicating movement of lever
N.	Normal	N.	
P.	Repeating	P.	Repeater
Q.		Q.	Local coil (2-element vane relay)
R.	Reverse-red	R.	Relay
S.		S.	Stick relay
T.	Track circuit	T.	
U.	Route indicator		
V.	Train stop	V.	Train stop
W.	Switch	W.	Switch-operating mechanism
X.	Bell	X.	Bell
Y.	Slotting	Y.	Slot
Z.	Treadle	Z.	Treadle
BX.	; AC. "positive energy"		Used for differentiating polarity of circuits
NX.	; AC. "negative energy"		
Shown (N.)			
B.	Battery feed		
N.	Battery return

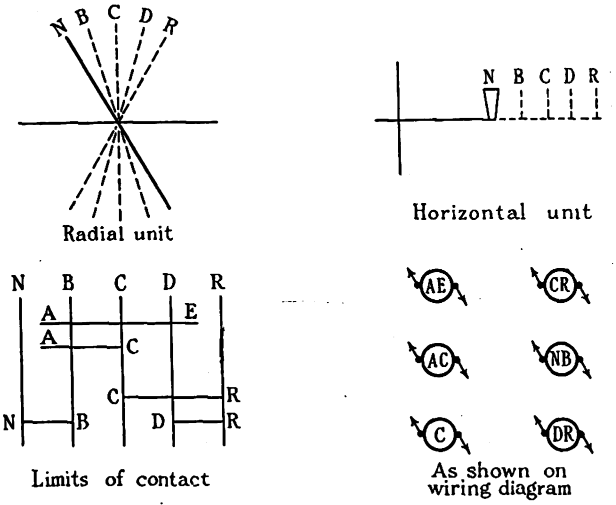

FIG. 3.—Some types of lever contacts and methods of showing them on wiring diagrams.

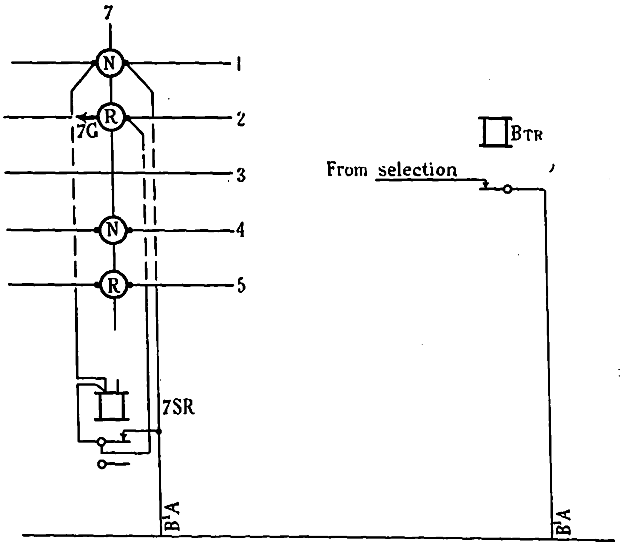

FIG. 4.

complicated. Fig. 3 shows what the author considers to be the best system to employ, and was arrived at by an association of railway signal engineers. The sphere of operation of a lever unit, whether it is a power frame, mechanical frame, or any other lever frame, is indicated by two vertical lines marked N and R, meaning the normal and reverse positions of that unit. Terminations of intermediate positions, that is where contacts are broken, are shown by intermediate positions B, C and D. C is obviously the central position of the unit. This applies to levers that operate radially or horizontally. The first half of this diagram explains where the various contacts make and break, and the second portion indicates how they are shown on wiring diagrams. An example of how and why these various contact positions are necessary may assist the reader to recognize the utility of this method of showing them. The normal and reverse contacts are necessary for point controls, tor selective purposes and for signal levers, the normal to pick up the stick relay and the reverse to close the signal control circuit. The C position may indicate a long contact made in the central position of lever operation to energize a special lock. The AB position would be used for signal indication circuits to close the lock circuit while the lever is being replaced to normal, and to break it when the lever is in the normal position and the lock no longer required.

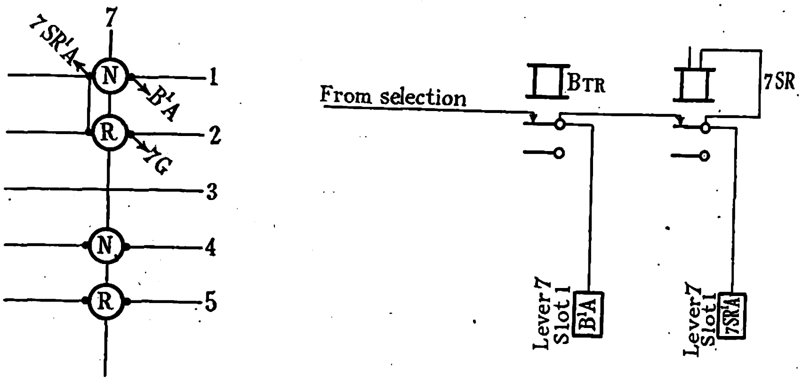

FIG. 5

Returning to the question of wiring diagrams and to the method that may be employed in drawing a wiring diagram for power frame interlocking, the various methods of doing this may now be discussed. Fig. 4 shows one method. In this case the contacts on the power-frame levers are drawn out in plan as they would be seen in the actual frame, the levers being drawn vertically and the rows of contacts horizontally. The track and line relays are drawn on the right of the diagram, and the main run of wires between power frame and relay cabinet is shown by one line. All wires from the relay contacts are drawn down to this run, and wires going up into the frame are shown going to the contacts in the same way. The terminal connected to the pivoted side of the relay contact is termed the armature and is known as A, while the terminal connected to the fixed contact side is known as the point and is termed P. Such connections are therefore known by the letter of the relay, the contact number, and whether the connection is an armature or point one. For instance, the end of the wire coming from contact B'A is lettered in this manner and a similar line similarly lettered, will be found going up into the power frame. This is the continuation of that wire going to the power-frame contact. A reference to Fig. 4 may make this clear.

This system is quite satisfactory for a small power frame containing some 30 to 50 levers, but even then it becomes very complicated with present-day methods employing check locking, track locking, route locking and proving. The diagram becomes a mass of lines and is difficult to follow quickly.

Fig. 5 shows another method of making the same kind of diagram and is used on at least one railway. In this case the lines are not fully drawn. A flag is drawn on the relay contacts bearing the number of the lever and the number of the slot in the frame where the contact may be found. It is then only necessary to follow the vertical line down that lever until the slot number mentioned is found. The arrow heads on the contact are similarly labelled and the whole circuit may be followed quickly. In this manner a geographical wiring diagram of a much larger frame may be drawn and is, in the author's opinion, a great improvement on the method shown in Fig. 4.

Although a geographical wiring diagram of a power installation is of great advantage from the point of view of locating an individual contact on a lever, it is also necessary to be able to trace through a complete signal selection with much more rapidity. This means that it is also necessary to have a circuit diagram; this will take the form of that shown in Fig. 6. In this case relay and frame contacts are numbered in order that they may be located, but at the same time the whole of the controls of an individual signal may be followed quickly. In America this type of diagram has been superseded by what is known as the written circuit. This is shown in Fig. 7. In this case all the contacts are drawn in one line, the difference between point and armature of a relay being indicated by a tiny arrow head or a small circle. The main advantage of this type of diagram is that it can be drawn quickly. In addition, a man who is used to power signalling work will have no difficulty in following it. A man who has had no previous experience, however, will probably find that the method shown in Fig. 6 is easier to understand.

One of the biggest problems which a railway signal engineer encounters is that of signalling an entirely new yard or railway. The location of signals themselves is not difficult, as it merely depends on known principles and traffic conditions that will have to be dealt with. These conditions may be such that he will be compelled to consider power working of some description, and in this case it may be difficult to determine exactly what system to adopt. Some points may already be determined for him. If electric traction is going to be employed it will be necessary to discover whether an insulated or an earth return is to be used. These considerations, together with the fact that signalling apparatus to-day is generally manufactured in types for which there is most demand, will lead him to some definite decision.

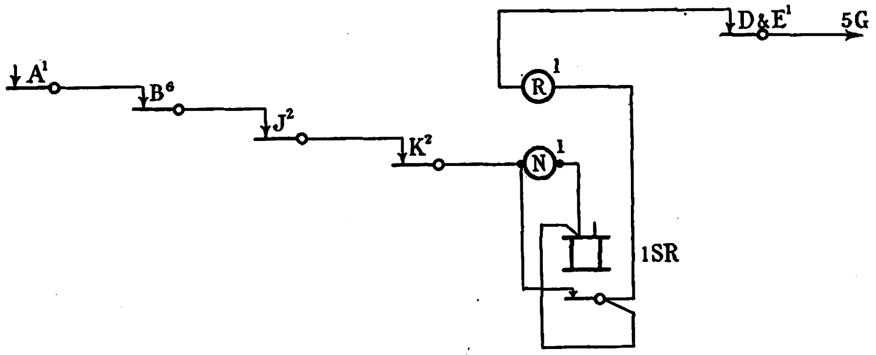

Fig. 6.

The best type of track circuit to employ will obviously depend entirely on the prevailing conditions. For track-circuiting a large lay-out where only steam traffic is in operation the ordinary battery track circuit is undoubtedly the best, since it is simple to operate and cheap to install. If d.c. traction with an insulated return is in use d.c. single-rail track circuits may be employed, providing the relays are of a polarized type. This is necessary, since faults are apt to develop on trains, and currents flowing back to the substation will traverse the track relay track coils in order to find a parallel circuit. Two relays must be used to each track, one at each end, so that, according to the direction of the earth current, one relay will be energized in the up position and the other in the down position. Large return currents, however, are apt to burn out the relays.

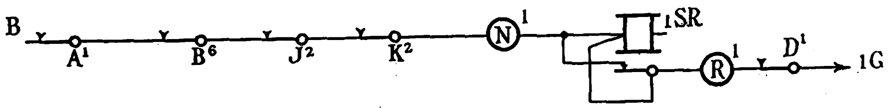

Fig. 7.

In this case it would be better to consider the single-rail a.c. track circuit. The tracks are "opposed" in this case so that in the event of the block joint insulation breaking down (for mechanical reasons) the adjoining track relay will be energized with reversed polarity. Two-element vane relays or galvanometer track relays may be employed. This type of track circuit is quite efficient and is to be recommended in the case of an electrified system with an insulated return. In some cases, however, failures will occur owing to train faults, the return leakage current sometimes saturating the iron core of the track-feed transformer.

Where an earth return is in use for traction purposes, impedance-bond track circuits are the only kind that may be adopted. They are not so efficient as the single-rail a.c. track circuit but their efficiency can be improved by adopting a resonated bond or a condenser feed.

The track circuit problem having been decided, the question of signal and point operation must be dealt with. In the author's opinion the best signal to adopt for outdoor purposes is the daylight colour-light signal. It is more efficient than the semaphore for sighting purposes where backgrounds are unsatisfactory. It also has no moving parts to get out of order. It is necessary in this case to use alternating current throughout, since the particular design of lamp used in this signal calls for low voltage and as this will be required at every signal location it is obvious that a transformer is the only solution. Two or three small transformers are placed in each signal, according to whether it is of the 2-position or 3-position type. If daylight signals are used all signals may be operated by alternating current from local track-feed transformers. The line relays, however, may be operated from batteries housed in or near the signal cabin. Point mechanisms of the battery machine type may also be employed and operated from the same source.

There is something to be said in favour of operating point machines by battery power. The battery may be kept floating and in the event of the power supply failing its capacity will keep the installation running, at least for several hours. During a total breakdown the chief cause of trouble in a busy yard is the operation of points. If all points and signals fail owing to a breakdown of supply these points have to be operated by winding a crank provided with the machine. If the signal line relays are operated by battery power they will be useless, since the signal lights themselves will be extinguished.

It would, however, still necessitate the attendance of the signal lineman in the signal cabin to release the electrical locks on the point levers.

The author is of the opinion that, under normal conditions, the ideal system for a yard is colour-light signals controlled by a.c. line relays and battery machine point operation.

In the case of an extension of a railway where the new terminal point may be some miles from the last sub-station, the question of battery machines may be looked at in a different light. If no direct current is available for charging purposes it will be necessary to run a d.c. main, and as this will be required at intermediate points for various roadside interlockings the capital cost may be appreciable. It may be argued that d.c. traction current will be available for traction purposes. The voltage will, however, have to be reduced, and this calls for motor-convertors or charging sets and therefore further expenditure. It may be necessary in this case to adopt a point machine with an a.c. motor working with a point controller at the site, since otherwise the power-frame contacts would have to break an appreciable current. Even if this is done there will be an appreciable drop on the main while the point is being operated, and this will have to be considered carefully beforehand. In this case the signal engineer, once he has decided to adopt electric power for his apparatus, should not hesitate to utilize all the known methods of counteracting loss. The voltage-drop on the main may be counteracted at chosen points by the use of condensers so that a leading current is taken to oppose the wattless component. It is also possible, where direct current is required for station lighting, to superimpose this on the a.c. main, employing chokes at distribution points. This system is adopted on one railway.

Fig. 8.

The type of system having been chosen, it will now be necessary for the man in charge of the drawing office to order his materials. One large factor in the choice of material is cable. There are three main types that may be employed. The first is armoured cable, buried in the ground, or supported above ground, the second lead-covered cable run in brackets on posts, and the third a pole line of either insulated or uninsulated wire. Dealing with the third first, this may be quite suitable for battery circuits where there are few lines, but for complicated interlockings it is out of the question.

The choice is thus narrowed down to lead-covered or armoured cable. The author considers that a lead-covered cable run neatly in specially designed brackets on posts or along walls is the ideal type to employ on a railway where there are no trespassers. Where there are many trespassers, as on some railways abroad, it is better to use an armoured cable and bury it in the ground, or support it in such a position as to be out of harm's way.

The method of running lead-covered cable is fairly straightforward. The ends of the cable are run direct into the holes in the various apparatus cases. In the case of armoured cables, many circuits in bulk will be carried by certain cables, specially near the signal cabin, and in order to tap the various circuits a disconnection box must be used. This should be designed to suit the various sizes of cables employed, and a double row of links or terminals should be placed inside and labelled accordingly, the location circuits being tapped out in the middle.

A cable chart is a necessity and should be employed by all railways on which there is power construction work. This will not only assist the indoor assistant to estimate his requirements, but will tell the outdoor assistant exactly what cables he has to run and what they are for. The apparatus to be placed at each location should also be indicated on the chart. This type of chart is shown in Figs. 8 and 9.

Great consideration should be paid to the signal cabin, since it houses all the controls of the outside apparatus. The upper portion will only house the upper portion of the power frame and the illuminated track diagram. Other requirements for the upper portion are equally applicable to a mechanical cabin and will therefore not be dealt with here. A word or two with regard to the illuminated diagram may, however, be of advantage.

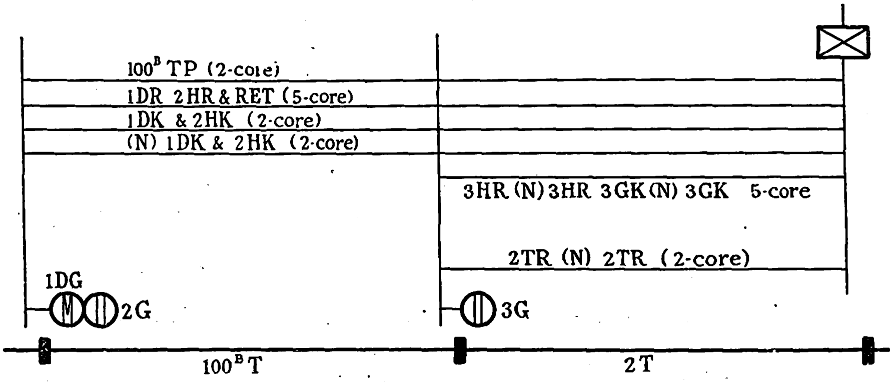

Fig. 9.

For a large and complicated diagram, strip lighting is the ideal method. To reduce the number of lamps, on some diagrams, spots or oval slots, placed in the middle of the diagram, are provided, the rest of the track circuit being painted on the diagram. This is satisfactory for a small diagram. For a large diagram strip lighting is, however, better from a signalman's point of view since it provides him with a more accurate idea of the conditions existing outside the cabin. The glass may be protected against the extra heat radiated by the additional lamps by thin copper gauze placed under it, but this will only be necessary where a very large variation of temperature is found.

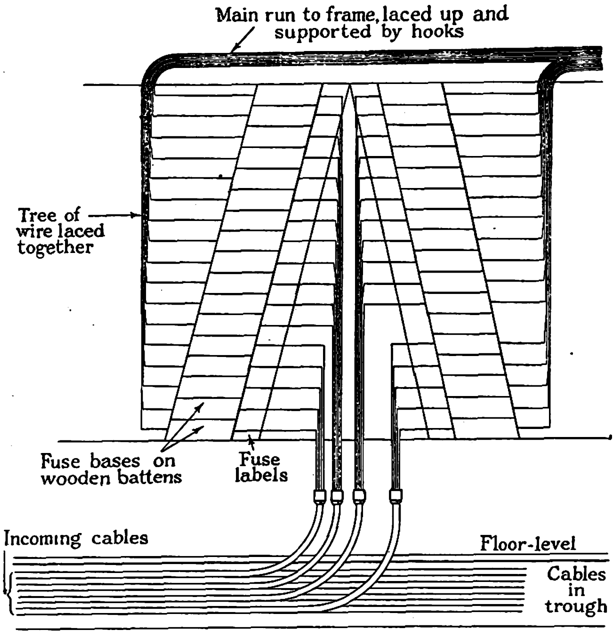
The track circuit indication itself is usually the natural colour of the lamps, which will vary from nearly white down to a light yellow, according to the voltage at that particular place and the efficiency of the lamps. Sometimes the voltage is low, with the result that the diagram tracks do not show up so brightly as usual. It has been thought that strip lighting puts an undue strain on the signalman's eyesight, as he is continually looking at the plan of the yard represented by brightly coloured lines. In order to minimize this effect some railways place a piece of coloured gelatine between the plain and frosted glass so that the tracks are shown up in colour when they are clear. This is certainly a good scheme and in the author's opinion green is the best colour to adopt, firstly because it is fairly restful to the eyes, and secondly because it is the colour chosen to represent a clear road.

With regard to visual signal indications, some railways place these in the illuminated diagram or in special cases on the instrument shelf. In the case of a power frame it is far better to place the visual indication at the top of the lever plate bearing the title of the lever, and this is now usually done.

The wires from the basement or relay room to the power frame may be run up through a hole in the cabin floor straight into the frame. With a large frame, however, of over 100 levers, with perhaps 10 to 20 contacts on each lever, the problem of accessibility arises and it is not easy to reach the contact terminals, which are vertically beneath the contacts, from the side panels of the frame when it is open. If possible it is better to place the frame over an aperture made in the floor and looking directly down into the relay room. The wires can then be directly run up into this place, and a suitable platform can be fixed underneath with a ladder from the floor of the relay room so that men may stand in comfort under the frame and reach the contact terminals.

Opinions differ widely as to the best method of accommodating relays. Some railways place them in glass-fronted wooden cabinets, others in steel cabinets. Inter-relay wires are laced up as they go from terminal to terminal, but those going from one shelf to another are usually run in closed trunking.

The author thinks that the best method is to place the relays on an open rack and in such a position that one may walk all round it if space permits. The wires should be run along the edge of each shelf on specially designed hooks made of wood. Inter-relay wires should be run in the same way and drop from the edge of the shelf to the relay below. Wires going from shelf to shelf should be run up the edge of the end posts, neatly laced up together and held in position by hooks. If relays are placed on an open rack and can be seen from both sides there is certain to be more light available for their examination and they can easily be kept clean. The racks may be made either of metal or wood or a combination of both. Metal uprights and cross members may be used with wooden shelves.



Main run to frame, laced up and supported by hooks

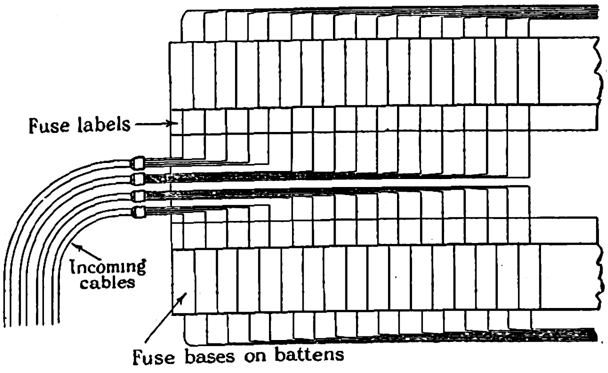
Fuse bases on wooden battens
Fuse labels
Incoming cables
Floor-level
Cables in trough

Fig. 10.

One popular method of accommodating fuses was to place them at the bottom of the relay cabinet, screwed on to a board with the wire pushed through a hole just large enough for one wire. Only the end of a wire going to a fuse base could be seen, the rest of the run being covered and out of sight.



Fuse labels
Incoming cables
Fuse bases on battens

Fig. 11.

As long as wires are covered or run in trunking they will always be the rendezvous of mice, rats and other pests, which destroy the insulation material. The author has often found the wires, in such cases, badly mutilated and the run full of dirt carried in by these animals.

Figs. 10 and 11 show two methods of fixing fuse-bases so that the wires can be run very neatly and on the open system. Both lend themselves to a very neat method of running in the cables. These may be brought up through the floor or through the end wall of the cabin and may be supported on cable brackets a foot or so above the floor or run in an open trough made in the basement floor. The ends of the cable, or at least the lead covering or armouring, may be cut away at the point where the cable runs up to the fuses, and the various cores run neatly upwards in a vertical direction.

Fig. 12.

Where the cabin floor is left open beneath the power frame and a platform is provided, a very neat arrangement is to build the relay rack to form three sides of a square around the floor aperture, the platform being fixed to the relay rack.

With regard to signal indication circuits, no circuit is really efficient unless it really detects whether the signal light is in or out. With daylight or lantern signals a circuit should be employed in which the return of all indicators is run back to the cabin and through the primary of a special indication transformer. The visual indicator over the power-frame lever plate is connected across the secondary so that if the signal light burns out the visual light in the cabin will also be extinguished.

Fig. 13.

With d.c. working the indication circuit may be identical, a resistance being employed instead of a transformer and the visual indicator being lighted by the voltage-drop across the resistance. This is shown in Fig. 12.

Point indication circuits should operate point indication relays in the cabin. If this is not done the indication locks on the point lever will be energized directly from the point detection cables and it will be necessary to take the signal selections reading over the points over contacts on the point lever and also through detection boxes on the ground before reaching the signal control relay. If a relay is used the locks are operated through a local circuit in the cabin. The signal selections may also be wired in the cabin so that the signal control cable leaving the cabin goes direct to the relay. From the point of view of testing this is a great advantage since all the apparatus will be centralized, and it is much better from an electrical point of view.

In automatic signal territory, where overlap track circuits are in use, the question arises as to whether the track circuit ahead controlling the signal should have its relay situated there or at the signal. A reference to Fig. 13 will make this clear. This shows an automatic starting signal at a station. $\mathrm{T}99^{\mathrm{B}}$ is the overlap on S100, the startor, and the track controlling the signal is $\mathrm{T}100^{\mathrm{A}}$ and the overlap on the next signal, with which we are not concerned in this instance. The relay for $\mathrm{T}99^{\mathrm{B}}$ will be at the signal, whilst the relay for $\mathrm{T}100^{\mathrm{A}}$ will be 1 000 ft. ahead. If it is retained there the signal control for S100 will have to be run up to this relay and back again, necessitating a 2-core cable. If track relay 100^{A} is placed along with track relay 99^{B} at the signal a 2-core cable for the track relay leads will still be necessary. The question of the resistance of the track relay leads will of course have to be considered, but if a track circuit employing a 2-element vane relay is used there will be no difficulty in this. This method may also be adopted on other types of track circuits with shorter overlaps. The advantage of placing track relay 100^{A} at the signal is again to provide centralization of apparatus and convenience of testing. On a tunnel section this may be more readily appreciated.

FIG. 14.

After a power interlocking or a power signalling system has been commenced it is important to arrange for some definite scheme of maintenance. All cables should be tested for insulation resistance at least once in two years and a chart should be drawn up so that each cable is tested periodically. As signal circuits are more or less standard on one railway, it will be convenient to draw up a cable testing-sheet somewhat on the lines shown in Fig. 14. From this it will be seen that if either side of the diagonal line is used each cable will be tested to earth and between cores without repetition.

A chart of apparatus-changing should also be drawn up so that any one piece of apparatus has only a definite spell of duty before it is removed for examination and overhaul.

With regard to signal failures, these are an evil which no railway can avoid, however efficient its system may be. As signal failures are likely to occur owing to causes over which the department has no control it is better to adopt some system of analysis so that at the end of a given period the signal engineer may be able to differentiate between his failures and see how many can be directly charged to him on the grounds of bad maintenance, defective design, etc. It is extremely useful if a proper analysis sheet be drawn up, dividing the signalling system into its individual component parts, and then subdivide these. The particular piece of apparatus that causes the most failures can then readily be identified and investigated with a view to making it more efficient.

Nowadays electric power can be obtained all over the country from outside sources and the signal engineer should not hesitate to take advantage of this fact. In addition it must be remembered that, as far as signalling is concerned, all traffic movements are generally thought out and assisted by the signalling department. The traffic department should be encouraged to bring its problems to the signal engineer and if he takes full advantage of all the resources available there will not be many problems which he will not be able to solve for them.

On one railway of which the author has knowledge the signal engineer is responsible not only for the signalling but also the current-rail connections, telephones, lighting and other auxiliary apparatus. It is not suggested that any particular railway might benefit by such an organization, but where it does exist there is no doubt that good results accrue. It must of course depend on the type of railway, for the signal engineer of an electrified railway or of a railway where there is an extensive electrified area must be an electrical engineer as well as a signal engineer.

THE LOADING OF TRANSFORMERS ON A THERMAL BASIS, WITH SPECIAL REFERENCE TO TEMPERATURE INDICATORS.*

By T. A. LONG, Student.

[ABSTRACT *of paper read before the* NORTH-WESTERN STUDENTS' SECTION *26th February, and before the* MERSEY AND NORTH WALES (LIVERPOOL) STUDENTS' SECTION *26th March,* 1929.]

The fundamental limit to the load a transformer will safely carry is the maximum temperature which its constituent material will stand without deterioration.

Excessive temperature of material if maintained for a fair length of time will cause deterioration of the insulation, and breakdown of the transformer will inevitably follow. It has been agreed almost universally that the maximum temperature allowable for continuous operation is 105° C., and, further, that the permissible difference between the maximum copper-temperature and the mean copper-temperature obtained by resistance is 10 deg. C. It has also been assumed that the ambient temperature should be 40 deg. C., thus leaving an allowable temperature-rise by resistance of 55 deg. C. The temperature-rise limits allowed by the British Engineering Standards Association for oil-immersed transformers are:—(1) 50 deg. C. measured by thermometer in the hottest oil, and (2) 55 deg. C. measured by the increase in the winding resistance.

It is evident that in actual service conditions the air temperature will seldom approach, and rarely, if ever, be maintained at 40° C. With certain favourable operating conditions and an accurate knowledge of the internal temperature conditions it is therefore possible to obtain safely a larger kVA output and even to exceed the above temperature-rise limits, without violating the intentions of the B.E.S.A.

There are three main methods of ascertaining the temperature of a transformer, viz. by reading a thermometer placed in the hottest oil, by noting the increase in the resistance of the windings, and by employing embedded temperature-detectors. To understand the limitations of each of these methods and to be able to interpret the results of such tests requires an understanding of the temperature distribution and the factors controlling the heat flow from the heated body to the surrounding cooling medium. The usual temperature-rise limit in transformers is the temperature-rise by resistance, and since the resistance of copper varies in direct proportion to the absolute temperature of the copper the ratio of the hot to the cold temperature of the windings may be obtained from the ratio of their hot to their cold resistances. Complete formulæ based on this fact are given in B.S.S. No. 171—1927.

The temperature-rise thus obtained is the average temperature-rise of the windings, and is the sum of the average winding-gradient and the mean oil-temperature, the hottest-spot temperature being the sum of the hottest-oil temperature and the maximum winding-gradient. The hottest-oil temperature and the winding gradient are quite independent of each other, and, within limits, each may be given any desired value. A measurement of the hottest-oil temperature therefore gives very little indication of the actual temperature of the transformer windings, and is thus no guide to the safe loading of the transformer. The ideal method of obtaining the true rating of a transformer is to measure it in terms of the hottest-spot temperature, and this is the function of a temperature-indicator. Some of the more important advantages of knowing the temperature of a transformer during operation are:—

(1) Insurance against damage from overloading, which should prolong the life of the transformer.

(2) Reduction in the installed kVA capacity of the transformer plant by the ability to increase the output of the transformer when the ambient temperature is below normal, when short-time overloads are required, and when the difference between the hottest-spot temperature and the average temperature is negligible.

(3) The possibility of conserving the cooling water for water-cooled transformers when the temperature of the ingoing water is below 25° C., and when the load is below normal.

There are a number of well-known schemes for observing the hottest-spot temperature of transformers. The essential requisites of any temperature-indicator are freedom from danger to the operator, simplicity of operation, and ability to indicate continuously, correctly and permanently the maximum temperature of the windings, under any condition of loading.

The most popular type of temperature-indicator in this country at the present time consists essentially of a dial thermometer the bulb of which is immersed in the hottest oil. Surrounding the bulb is a small resistance coil which is connected to the secondary of a current transformer through the primary winding of which the load current flows. The temperature of the resistance unit is so adjusted that it increases the temperature of the bulb by an amount equal to the maximum winding-gradient.

The resistance unit, being insulated from the main transformer winding, does not subject the operator to the danger of high potentials. If proper attention is given to the thermal design of the transformer there will be no need to have a separate resistance unit and current transformer for the high- and low-tension windings respectively. It is a popular misconception that the high-tension winding reaches a higher temperature than the low-tension winding. This is not so; it is purely a matter of design, and the relative temperatures of the windings may be varied at will by the designer.

---

* A Students' Premium was awarded by the Council for this paper, and it is the practice of the Council in such cases to publish the paper, in full or in abstract, in the *Journal*.

Since the thermal time-constant of the resistance unit is very small (2 or 3 minutes), its temperature very rapidly follows any changes in the loading, and the indications of the instrument follow these changes with practically no time-lag—an important feature if the transformer is subjected to sudden and heavy overloads. The instrument can be calibrated directly in hottest-spot temperatures or in percentages of the maximum load the transformer will safely carry, and may be fitted with a warning or tripping device to operate when the transformer reaches a dangerous temperature.

One possible objection to thermal loading is the resultant poor voltage regulation. An examination of this objection shows that, assuming the very worst conditions, the effect of loading transformers at their true thermal rating should not give an increased voltage-drop of more than 1 per cent. Considering the investment represented by the transformers on a large supply system, it is evident that a means of loading transformers to the limit of their true rating is necessary if the capital invested is to be reduced to a minimum and the transformers kept in good operating condition throughout their useful life. It is impossible to stress too much the importance of replacing transformers as soon as their thermal capacities have been exceeded.

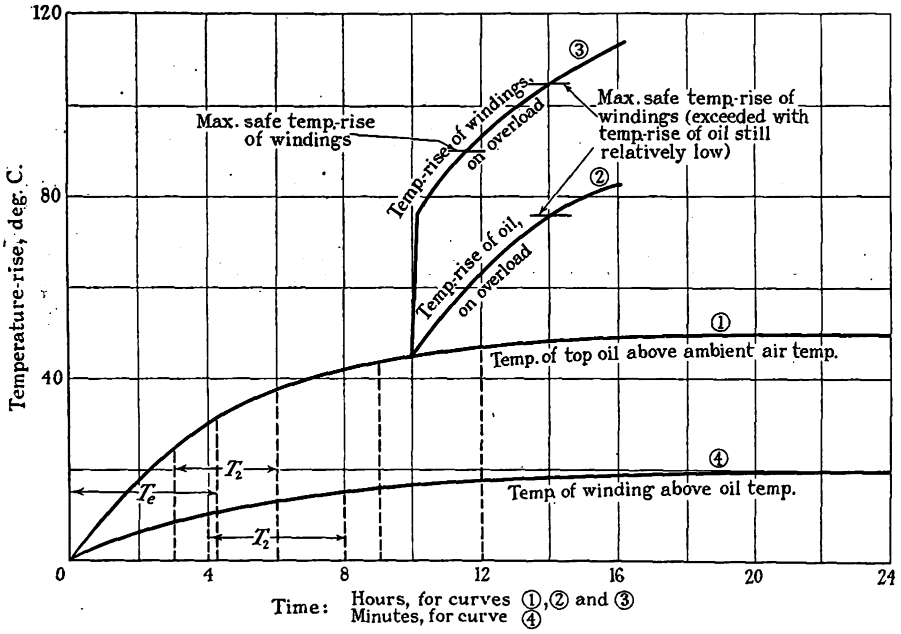
The author wishes to acknowledge his indebtedness to Messrs. Ferranti, Ltd., for allowing him to prepare the paper, and to members of the staff of the company, and of the English Electric Co., Ltd., for their valuable help and suggestions while it was in the draft stage.

APPENDIX.

LIST OF SYMBOLS.

θ = ultimate temperature-rise in deg. C. above ambient temperature.
t = time in hours or minutes from start of temperature-rise test.
ϕ = temperature-rise in deg. C. above ambient temperature.
ϕ_1 = temperature-rise in deg. C. after time t_1.
ϕ_2 = temperature-rise in deg. C. after time t_2.
ϵ = 2·718.
T_e = exponential thermal time-constant.
T_2 = binary thermal time-constant.

Some of the more useful relations of a heating curve (see Figure) are given here for reference purposes. Owing to the complexity of thermal relations among the different elements of a machine the temperature-rise may depart somewhat from a simple exponential curve, but in many cases it conforms to such a curve sufficiently closely for practical purposes. When the temperature-rise of a machine follows a known law it is easy to predict the course of the change in temperature if the load is changed abruptly from one long-continued steady value to another. If the load is changed in a less simple way, so that the one thermal transient is started before the preceding transient or transients have substantially terminated, the predetermination of the corresponding temperature becomes very complex. An instrument such as a winding-temperature indicator will automatically take into account the preceding loading history of the transformer when indicating the safe load which may be taken from the transformer.



Typical temperature-rise/time curve of a transformer, showing the relative winding and oil temperatures with 25 per cent overload.

Ambient air temperature = 15° C. (59° F.)
Winding temperature-rises above ambient air are obtained by adding the winding rise above oil to the oil rise.

The exponential thermal time-constant (T_e) is that interval of time during which the temperature-rise comes within $1/\epsilon$, or $1/2 \cdot 718$, or $36 \cdot 8$ per cent of the final temperature-rise, i.e. the time taken to reach $63 \cdot 2$ per cent of the ultimate rise. In a period $2T_e$ the rise will come within $1/\epsilon^2$, or about 13 per cent, and in a period $3T_e$ within $1/\epsilon^3$ or about 5 per cent of the ultimate rise.

The binary thermal time-constant T_2, suggested by Kennelly, is now used largely in America although it does not appear to have gained much popularity in this country. It is claimed that the binary time-constant is the obvious practical constant presenting itself for use, as it is an easy constant to remember and explain, and bears a fixed relation to the exponential time-constant; the difference being that it has a base of 2 instead of $\epsilon(2 \cdot 718)$. The binary time-constant T_2 may be defined as that interval of time during which the temperature-rise comes within one-half or 50 per cent of the final rise. In a period $2T_2$ the rise will come within $(\frac{1}{2})^2$, or 25 per cent, and in $3T_2$ within $(\frac{1}{2})^3$ or $12\frac{1}{2}$ per cent of the ultimate temperature-rise. The two time-constants are always connected by the relation

$$T_2 = 0 \cdot 69315\, T_e, \text{ or } T_e = 1 \cdot 4427\, T_2.$$

The general formula for a heating curve is

$$\phi = \theta(1 - \epsilon^{-t/T_e})$$

Therefore

$$1 - \phi/\theta = \epsilon^{-t/T_e} = 2^{-t/T_2} \quad . \quad . \quad . \quad (1)$$

This may be plotted as a straight line on semi-log paper. $(\theta - \phi)/\theta$ is the deficiency, and ϕ/θ the attainment. A temperature-rise (ϕ, t) curve having been obtained by test, it is easy to determine by inspection whether the curve follows equation (1). The ambient temperature should, of course, be kept constant during the heat run, or if it has slightly varied the curve should be corrected. The final temperature-rise is also necessary, either from test-results or by extrapolating from the curve. The time from 0 to $\frac{1}{2}\theta$ is measured along the time axis of the curve. This should be the binary time-constant T_2. In another such period of time the further temperature-rise should be $\frac{1}{4}\theta$, in a third such period of time the further temperature-rise should be $\frac{1}{8}\theta$, and so on. If these relations hold satisfactorily the curve may be regarded as exponential, from a practical standpoint.

The formula for deriving the ultimate temperature from an incomplete temperature-rise curve is

$$\theta = \frac{\phi_1}{2 - (\phi_2/\phi_1)} \text{ deg. C.}$$

where ϕ_1 is the temperature-rise at the end of t_1 hours, and ϕ_2 is the temperature-rise at the end of t_2 hours, t_2 being $2t_1$ hours. It is assumed that the curve is exponential, that $\phi = 0$ at the start, and that the ambient temperature remains constant throughout, or has been corrected for. Thus, if $\phi_2 = 1 \cdot 5\phi_1$, it follows that $\theta = 2\phi_1$, and $t_1 = T_2$.

DISCUSSION ON
"THE ROTOR BEARINGS OF ELECTRICITY METERS."*

Mr. E. G. Sandmeier (*communicated*): The author recognizes the obscurity of the problem of worn bearings, and points out that the evidence provided by life statistics of jewels is so contradictory that no conclusion as to the cause of wear can be drawn from them. The following observations may perhaps help to throw some light on this rather complex question. They are based upon systematic researches, extending over several years, which aimed at producing a suitable rough material and making from it a reliable jewel bearing for use in electricity meters and other sensitive measuring instruments. The investigations were concerned only with ruby and sapphire bearings, and dealt exclusively with defects directly connected with the raw material and the manufacture of jewels. All other causes of rapid wear, such as inappropriate pivots, badly mounted jewels, defective protection of the bearing against dust, jewels damaged by the obsolete needle test, or dirt in the cup of the jewel when a new meter is installed, were ignored. When tracing the causes of defects or over-rapid wear in bearings, an important factor is generally left out of consideration. Little or no attention is given to the fact that the sapphire is not an amorphous material, having the same properties in all directions, but is endowed with a crystalline structure which plays an important part in qualifying it to act as a long-life jewel bearing. In most of the ordinary meter jewels, natural and synthetic, the position of the cup was, until a short time ago, fixed regardless of the structure of the material. What this means can be seen clearly in the photo-micrographs of Fig. A (natural sapphire) and Fig. O (synthetic ruby). In these bearings the pivot rotates perpendicularly on a cross-section of the layers forming the stones. Because of the more or less pronounced difference in hardness between the layers of different colours, and since the angles formed by the crystal faces of the hexagonal prism (Fig. A) of a natural sapphire are harder than the flat sides, such jewels will very quickly wear out the pivot. It was therefore of interest to ascertain whether the faulty bearings mentioned in the paper confirmed the results obtained with other worn jewels. By the courtesy of the author I was able to examine 36 of the defective jewel bearings referred to in Table 1 of the paper. A first inspection of these jewels revealed the fact that all were of a rather poor quality, the majority being polished in an inferior fashion, and not a few of the stones exhibiting serious flaws. None was entirely free from defects of material or workmanship, each having at least one of the capital defects mentioned in the table, and in general they gave the impression of being of the so-called "War" quality. As far as can be judged by the condition of these used jewels, all of which show more or less deep abrasions, the real causes of failure are, first, a very defective polish on the surface of the cup, and secondly defects of material, in some cases so serious that they should have led to the rejection of the jewels concerned. A third cause of wear may have been the broken edges of the cup, the minute particles of material from which form an excellent grinding medium. The possible sources of wear are so numerous that it is rather difficult to say exactly what caused the failure in each particular case. It is highly probable that a combination of the various defects helped to shorten the life of the respective jewels. Figs. B to O are reproductions of photo-micrographs of some of the jewels whose principal defects of material and workmanship are set out in the table. Fig. B represents inclusions of a natural sapphire, probably consisting of rutile-needles. Fig. C shows big inclusions of another nature in a natural sapphire. Fig. D is a side view of a natural sapphire full of liquid inclusions. Fig. E shows a striated natural sapphire, the cup of the jewel being placed on a cross-section of striæ. The black spot on the left is a hollow cut out by the surface of the bowl and filled up with rust from the pivot. Fig. F represents another typical striated natural sapphire exhibiting signs of internal strain. Figs. G and H show the same natural sapphire, the first being a reproduction of the abrasion, and the second showing a field of fine bubble-like inclusions. Fig. J illustrates a central circular abrasion, as well as minute inclusions. The black half-moon on the right of the abrasion is a crack running almost horizontally into the stone, and filled with rust from the pivot. Fig. K shows the very badly polished surface of the cup of a natural sapphire, with a deep central abrasion. The radial, slightly curved scratches are typical of the first polishing operation. They have not been removed entirely by the following process of giving a high polish to the cup. Fig. L shows a synthetic ruby full of small gas bubbles, whilst Fig. M shows the same jewel. The edge of the cup is completely smashed. Fig. N represents a synthetic ruby containing big gas bubbles. Fig. O is a photo-micrograph of a synthetic ruby, showing the slightly curved layers, i.e. the typical

structure of the synthetic coloured corundum, the cup being placed on a cross-section of the material. The nature of the various defects of the 36 faulty jewels can be so easily established, and the flaws are so serious, that it seems impossible to ascertain whether the fact of placing the cups without regard to structure was another cause of over-rapid wear. However, it is noteworthy that the jewels with the deepest abrasions are in general those in which the cup is placed on a cross-section of the structure. Inspection of the 36 defective jewels leads, in the first place, to the conclusion that these stones cannot be taken as a basis for judging the suitability of ruby or sapphire for meter bearings. The examined jewels had to break down, and it would have been surprising if they had done anything else. Secondly, the investigation gave evidence of the considerably higher risk of failure in the case of natural sapphires, nearly 95 per cent of the natural stones examined being infected with flaws of material, inclusions, striæ and other areas of weakness which rendered them undesirable as material for bearings. The synthetic rubies show 53 per cent of defects of material, all of which can easily be avoided to-day because the quality of the synthetic stone has been greatly improved since its first appearance on the market. In this connection it is interesting to note that Lieut. R. J. Bray, in his standard work on "Pivots and Caps in Compasses," published in 1917, foresaw the possibility of improving the quality of synthetic corundum and making it the "ideal material for mechanical purposes." During the last few years these improvements have been achieved, at least so far as they concern the products of the factory with which I am associated. Indeed, if the synthetic rubies known until 1917 were full of striæ and inclusions, and inclined to split and shatter, the special-quality synthetic sapphire of to-day has no inclusions whatever. This new material has the hardness of the natural sapphire, but not its defects; it is much tougher, less brittle, and not liable to the failures to which the native product may give rise. The uniformity in hardness and in toughness is obtained partly by directing the operation of fusing and crystallizing in such a manner that the creation of internal strains in the growing crystal is avoided or reduced to a harmless minimum, and partly by selecting specially prepared pure alumina containing no colouring agents whatever and giving a transparent, colourless sapphire. The tendency of the synthetic ruby to split and shatter, referred to by Lieut. Bray, is due more to internal strains than to inclusions. By locating the cup according to the structure of the material a further improvement, and one that could not have been foreseen 12 years ago, has been achieved. Fig. P is an internal view of a synthetic ruby in which the cup is orientated according to the structure. The slightly curved layers forming the synthetic stone can be plainly seen. In this jewel the head of the pivot turns on a plane formed by one or more surfaces of the layers, but never on the edges of the latter. In the case of the natural sapphire also it is theoretically possible to locate the cup according to the crystalline structure of the stone, but this could hardly be done in practice because it would be difficult to find enough natural sapphires without flaws or striæ. Furthermore, the price of a natural jewel selected in this way by scientific research would be much too high, because a great number of stones would usually have to be examined before one capable of passing all the tests could be found. On the other hand, industry disposes to-day of the white or colourless specimen of synthetic sapphire, as shown by Fig. Q. This photo-micrograph is an internal view just below the cup, of a synthetic jewel, made of a special-quality white sapphire. No characteristics of structure can be distinguished, the material containing no colouring agent whatever, being absolutely uniform, and without any flaws. The cup is nevertheless correctly located according to the structure, and this type of jewel is therefore the best at present available, the diamond excepted, for use as a long-life bearing. It has been perfected as the result of a thorough study of faulty bearings and the possible causes of wear, and this is perhaps the only way which will lead to a solution of the problem of the apparent contradiction to be found in life statistics of jewels belonging to the same class of minerals.

Mr. W. Lawson (*in reply*): It is disturbing to read Mr. Sandmeier's conclusion that none of the jewels which I submitted to him was originally free from defect of either workmanship or material. The fault is clearly with the meter manufacturers, and although the majority of these bearings were purchased during the War period they were not necessarily of the so-called "War" quality, because my statistics show that the pre-War jewels associated with the same make of meter had approximately the same percentage of defectives.

Before the meters were calibrated and put into service the jewel cups were carefully cleaned and subjected to the needle test. Unfortunately it was not then my practice to have new jewels examined under the microscope, otherwise some of the flaws, inclusions, and the inferior polish which, Mr. Sandmeier states, characterized these jewels may not have passed entirely unnoticed. Mr. Sandmeier would appear to have made out a strong case for adopting the synthetic stone, but I am able to say that good results are being obtained from natural stones in single-phase meters at the present time. I appreciate the very thorough way in which Mr. Sandmeier carried out his investigations on the jewels I submitted to him and I consider that he has provided us with much valuable knowledge. I have no doubt that if the greatest possible care is exercised in selecting the material of both the jewel and pivot and if they are shaped with the utmost precision and given the highest possible finish we shall in the future hear very little of the failure of meter bearings.

DISCUSSION ON

"AN INVESTIGATION OF FREQUENCY VARIATIONS IN INDUCTION WATT-HOUR METERS."*

Dr. A. Callsen (*communicated*): The paper contains a great deal of experimental data relating to the frequency variations of induction meters, but the authors' theoretical explanations of the origin of torque fluctuations with frequency fluctuations, and the conclusions which they deduce therefrom as to the disc inductivity are, however, open to question. The authors assume that the torque is proportional to $\cos^2 \theta$, where θ is the angle of lag of the disc current in relation to the disc e.m.f., and ascertain the torque error at various frequencies for a time-constant $\alpha = 0 \cdot 0005$ ($\theta_{f=50} \sim 9°$) and $\alpha = 0 \cdot 001$ ($\theta_{f=50} \sim 17 \cdot 5°$). As θ increases with higher frequencies ($\tan \theta = 2\pi \times f \times \alpha$) they obtain with higher frequencies a decrease of torque proportional to $\cos^2 \theta$, and they make use of this observation to determine the time-constant α by measuring the torque at two different frequencies. In this connection I wish to make the following observations:—

(1) The torque of the induction meter is proportional not to $\cos^2 \theta$ but to $\cos \theta$, as can be deduced from the torque formula of the meter

$$\begin{aligned} D = {} & C' \times \Phi_I \times \Phi_V \times f \times \sin (\psi - \theta_I) \\ & + C'' \times \Phi_I \times \Phi_V \times f \times \sin (\psi + \theta_V) \end{aligned}$$

where D = torque; Φ_I and Φ_V = the current flux and voltage flux respectively; ψ = angle between Φ_I and Φ_V; and θ_I and θ_V = angle of lag of the disc current with the disc e.m.f. If in this equation $C' = C''$ and $\theta_I = \theta_V$ then we get

$$D \propto 2 \times \sin \psi \times \cos \theta \text{ and}$$
$$D \propto \cos \theta \text{ if } \psi \text{ is constant}$$

(2) The calculation of the frequency error on the basis of the alteration of the angle θ does not take into account the real causes of the frequency errors. Exhaustive calculation only shows that the influence of the disc inductivity with the variations of the frequency is very small, at the most 1 per cent with change of frequency from 50 to 100 cycles per sec. with an aluminium disc 1·2 mm thick. The prime cause of frequency error is rather the change of the voltage damping in the reverse action of the disc current on the magnetic circuit of the voltage and current fluxes. The reverse action occasioned through the loading of the fluxes by the secondary current in the disc and short-circuited windings on the poles causes a diminution of the driving fluxes at higher frequencies. This phenomenon has long since been theoretically explained † and has also more recently been treated mathematically.‡ These deductions are confirmed by Figs. A and B, which are experimentally developed frequency-error curves. These curves, which were obtained in the meter research laboratory of Siemens-Schukertwerke, refer to a single-phase meter with a phase displacement of 90° produced by a magnetic shunt on the voltage iron. As the 90° displacement was obtained without any short-circuit winding on the voltage pole, the flux changes are caused *solely* by the reverse action of the disc. The errors of the voltage-driving flux Φ_V and of the current-driving flux Φ_I are measured by the alternating-current compensator. The brake factor of the voltage-driving flux was experimentally obtained and the brake curve ΔB_r calculated on the basis of this factor. Fig. B shows the sum of these errors and, for comparison, the error curve as actually ascertained from measuring the meter revolutions.* A similar method was adopted for a second meter in which the 90° displacement was produced not by a magnetic shunt on the voltage iron but only by strong short-circuiting rings at the voltage pole. The resultant error curve, together with the measured-error curve, is shown in Fig. C. The steep bend at frequencies below 50 cycles per sec. is due to increased voltage damping and the effect of the ohmic voltage-drop in the voltage coil. As no magnetic shunt is present in the voltage iron the magnetization current i_m and hence also the ohmic drop are so large that at lower frequencies ($i_m \propto 1/f$) an appreciable decrease of the e.m.f.—and

[‡] A. CALLSEN: *Archiv für Elektrotechnik*, 1929, vol. 23, p. 40.

[*] In summing the errors the effect of the angle error on the torque was also considered. With $f = 100$ this error was about $- 0 \cdot 2$ per cent.

consequently of the total flux—results. At higher frequencies smaller errors were found than in the case of the meter considered in Figs. A and B. This again is partly due to the voltage damping and the ohmic voltage-drop but also partly to the fact that in a magnetic circuit without any magnetic shunt the reverse action of the secondary current is smaller. In spite of the strong short-circuiting rings the effect of the flux is smaller than in the case of the first meter. In both cases the agreement between the error curve compiled from individual errors and the curve resulting from measuring the revolutions is proportionately good. At most of the frequencies the error ascertained by measuring the revolutions is smaller than the sum of the individual errors, which goes to show that the influence of disc inductivity lies within the limits of errors of measurement.

(3) From the foregoing it follows that the determination of disc inductivity by measuring the torque at two different frequencies according to the authors' method must produce much too high a value; for the decrease of torque at higher frequencies is due almost exclusively to the diminution of the driving fluxes in consequence of the strengthened disc reverse action, and in a very small degree to the disc inductivity. Nevertheless this method of determining the disc inductivity would be free from objection if, when measuring the torque, the change in the driving fluxes is also taken into account by measuring the flux. As, however, the differences would be very small this determination of the angle θ might be inaccurate.

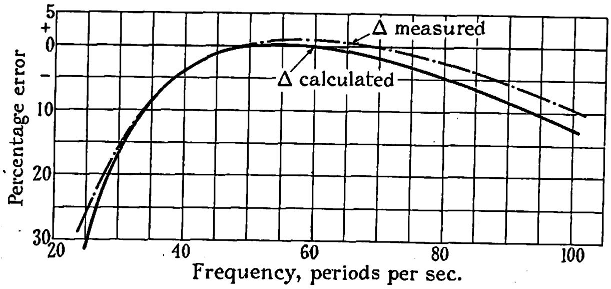

FIG. C.—Corresponding curves as in Fig. B, but for a meter without magnetic shunt on the voltage iron and with 90° phase displacement obtained by short-circuited windings on the voltage pole. Constant terminal voltage V.

Messrs. A. E. Moore and **W. T. Slater** (*in reply*): The torque formula given by Dr. Callsen for the meter is incomplete. It takes account of the magnitudes of the fluxes and the phase of the eddy currents, but it omits the magnitude of the eddy currents. The magnitude of the voltage eddy current is $e_V/Z = e_V/R \cos\theta$, where Z is the impedance and R the resistance of the eddy-current path. Thus the torque formula should contain another $\cos\theta$ factor. The same formula obtains in the case of the induction motor, and the torque in that case is also proportional to $\cos^2\theta$.

In the second part of his remarks Dr. Callsen states, firstly, that the inductivity of the disc is so small as to have practically no effect, and then proceeds to say that the eddy currents induced in the disc have a powerful demagnetizing effect on the poles. These two statements appear to us to be contradictory. If the inductive effect of the disc is negligible then the eddy currents are in quadrature with the inducing fluxes, and the demagnetizing components are negligible. If, however, the demagnetizing components are appreciable then the eddy currents must lag considerably behind the induced e.m.f.'s, since the induced e.m.f.'s are in quadrature with the inducing fluxes. We submit, therefore, that the explanation put forward by Dr. Callsen is a confirmation of the theory which we ourselves have given. The point is further illustrated by the vector diagram, Fig. D, which is drawn for unity-power-factor conditions on the assumption that the effect of the disc inductivity is negligible. Referring to the diagram, e_I and i_I are in phase with each other and produce a flux Φ_{EI} also at the same phase position. Similarly e_V, i_V and Φ_{EV} all have the same phase. The resultant voltage flux Φ_{VT} is therefore composed of Φ_V and Φ_{EV} and differs in phase from Φ_V by an angle δ. The torque of one pair of components is therefore proportional to

$$i_I \times \Phi_{VT} \times \cos\delta = i_I \times \Phi_V$$

for Φ_V and Φ_{EV} are at right angles, since the time-constant of the disc is zero by assumption, and therefore $\Phi_{VT} \cos\delta = \Phi_V$. Hence, no matter how much the flux is altered

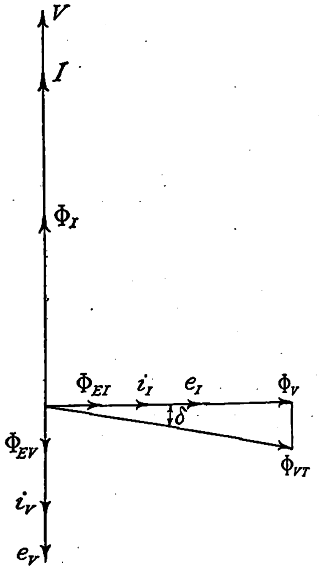

FIG. D.

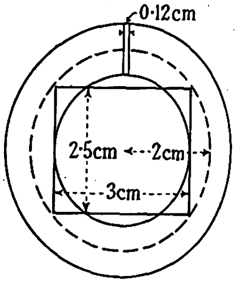

FIG. E.

by the corresponding eddy current, the resultant effect on the torque is nil, so long as the disc is assumed to have zero time-constant. We have examined a meter made by Messrs. Siemens-Schuckert and from the details of the meter have arrived at the following approximate result. Taking the voltage poles (Fig. E), area of pole-faces $= 2\cdot 5 \times 3 = 7\cdot 5$ cm^2, and length of air-gap $= 0\cdot 3$ cm. Assuming the iron circuit to have a negligible reluctance compared with the air-gap, and assuming that the eddy-current path is defined by, say, a ring in the disc, the ring having a mean radius of 2 cm and a cross-section of 1 cm × 0·12 cm, the time-constant of the disc, if of copper, works out as follows:—

$$L = \frac{4\pi \times 7\cdot 5}{0\cdot 3 \times 10^9}$$

$$R = \frac{1\cdot 7 \times 2\pi \times 2}{0\cdot 12 \times 10^6}$$

$$L/R = 0\cdot 002 \text{ (approx.)}$$

For an aluminium disc of the same dimensions L/R would be approximately 0·0012. These figures for the time-constant, though only very approximate, appear to indicate that the values for the time-constants which we obtained experimentally are not excessive. The air-gap between the current poles is generally larger than that between the voltage poles, and the time-constant of the disc when between the current poles would be less than when between the voltage poles. The figures obtained experimentally for the time-constants probably approximate to the mean values of the two.

In this connection we should like to revert to Mr. Fawssett's contribution to the discussion (page 1033). We think that the experiment which Mr. Fawssett describes gives results for that part of the disc which is between the current poles, and if he repeated the experiment with the rotor current embracing the voltage flux instead of cutting it the results would be interesting.

THE BENEVOLENT FUND.

32ND ANNUAL GENERAL MEETING, 15TH MAY, 1930.

Col. Sir Thomas F. Purves, O.B.E., took the chair at 5.30 p.m.

The notice convening the meeting was taken as read.

The minutes of the 31st Annual General Meeting held on the 9th May, 1929, were also taken as read and were confirmed and signed.

The Report of the Committee of Management (see below) and the Statement of Accounts for the year 1929 (see page 768) were presented and, on the motion of the Chairman, seconded by Mr. P. Rosling, were unanimously adopted.

On the motion of the Chairman, it was resolved that Mr. J. Attfield, F.C.A., be appointed Honorary Auditor for the year 1930.

The Chairman reported that, under Rule 15, the Council had appointed the following Committee of Management for the year 1929–30:—

The President (*ex-officio*).

Major B. Binyon, O.B.E., M.A., Mr. H. Marryat, Col. R. K. Morcom, C.B.E., M.A., Mr. F. W. Purse, Lieut.-Col. W. A. Vignoles, D.S.O., Mr. H. T. Young,	representing the Council;
Mr. A. F. Harmer, Mr. S. R. Mullard, Mr. P. Rosling,	representing the Contributors;

and the Chairmen of the Local Centres in the United Kingdom and Ireland.

REPORT OF THE COMMITTEE OF MANAGEMENT OF THE BENEVOLENT FUND FOR 1929.

CAPITAL.

The Capital Account stood on the 31st December, 1929, at £14 242 8s. 4d., which is invested.

RECEIPTS.

The Income for 1929 from dividends, interest and annual subscriptions was as follows:—

	£	s.	d.
Dividends on investments ..	681	15	6
Interest	32	16	10
1 056 Annual Subscriptions ..	606	11	0
	£1 321	3	4

In addition to the foregoing, the Fund benefited during the year by the following amounts, many of which are non-recurring donations:—

	£	s.	d.
South Midland Electrical Engineers' Ball Committee	78	15	0
Electrical Engineers' Ball Committee	50	0	0
Liverpool Centre, Golf Tournament	38	14	4

2 429 donations of under £5	948	13	7
	£1 489	14	3

The accumulated balance of the Income and Expenditure Account amounted on the 31st December, 1929, to £2 258 9s. 7d., of which £1 552 16s. 4d. was invested and £500 was on deposit with the Institution Bankers.

DONORS AND SUBSCRIBERS.

Lists of the names of donors and subscribers are issued to members of the Institution annually.

The Committee of Management desire to acknowledge their indebtedness to the donors and subscribers, and to intimate that, apart from donations, the Committee will be grateful for annual subscriptions of any amount. The Committee are anxious that the Capital Account should be steadily augmented, so as to strengthen the financial position of the fund.

LEGACIES.

The Committee have to report legacies of £100 each from the late Dr. C. S. du Riche Preller (Member) and the late Mr. H. Louis Leach (Member), which amounts have been invested.

GRANTS.

Applications for assistance were made by or on behalf of 35 persons during 1929, and the Committee, after due consideration, made grants in 32 cases.

The total amount of the grants was £1 538 15s. 0d.

WILDE FUND.

The Capital Account stood on the 31st December, 1929, at £3 049 16s. 2d., all of which is invested and brings in an annual income of about £112 5s. 0d.

The balance standing to the credit of the Income Account (from which, under the Trust Deed, full Members only can benefit) on the same date was £87 17s. 5d.

Grants amounting to £92 were made from this Fund during the year.

PROCEEDINGS OF THE INSTITUTION.

800TH ORDINARY MEETING, 27TH FEBRUARY, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 13th February, 1930, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

The President drew attention to the portrait of Sir Joseph Swan by Mr. Wal Paget, which had been presented to the Institution by Sir Charles Parsons and had been hung in the Lecture Theatre. He asked the donor to say a few words about the portrait and its subject.

Sir Charles Parsons: It is my pleasant duty to say a few words about my old friend Sir Joseph Swan. So much has lately been said about him on the occasion of the jubilee of the incandescent electric lamp, that it is superfluous for me to say very much on this occasion. In the Institution *Journal* for February, 1929,* will be found an account of the proceedings in connection with the jubilee of the invention of the carbon incandescent electric lamp by Sir Joseph Swan in 1878. The same issue of the *Journal* also contains † an address by Mr. Swinburne, entitled " Sir Joseph Swan's Electrical Work." Mr. Swinburne was employed in his younger days by Mr. Swan (as he then was) at Newcastle-upon-Tyne, just at the time when Swan was developing his electric lamp, and they were close friends. Mr. Swinburne elaborates the many and considerable difficulties met with by this pioneer at that time, and the great technical skill and patience which Swan employed and which brought about the success of the invention. In the same publication ‡ Sir Ambrose Fleming gave some brief personal recollections of Swan's part in the invention of the carbon incandescent electric lamp, and stated that it is beyond question that Sir Joseph Swan was one of the great pioneers whose investigations and inventions gave us the incandescent electric lamp in its earliest practical form, and that the credit for that epoch-making invention cannot be claimed for Mr. T. A. Edison alone. In the late seventies, while serving an apprenticeship at the Elswick works of Sir William Armstrong, Mitchell and Co., I became acquainted with the future Sir Joseph Swan, and we had many interesting discussions then and at subsequent periods. In the early eighties he often inquired how the steam turbine was getting on, always in the most kindly, sympathetic and encouraging way. Swan had an interest in many things besides his lamp, among them rapid photographic dry plates, of which I believe he was to some extent the inventor. We also talked about improvements in the navigation facilities of the Tyne, and he was very interested in, and often used to speak about, the building of the High Level Bridge over the Tyne by Robert Stephenson. Swan's kindly face is admirably reproduced in this portrait by Mr. Wal Paget, and I venture to think that the members of this Institution will agree with me in suggesting that the Council are to be congratulated on having secured the services of so excellent an artist and one, moreover, who had the advantage of being personally acquainted with Sir Joseph Swan.

The President: In a case of lavish generosity such as this, Sir Charles Parsons is hardly the kind of person who would either expect or enjoy any elaborate protestations of gratitude. I will ask you to express in the usual manner your hearty thanks to Sir Charles Parsons.

The vote of thanks was carried with acclamation.

The Faraday Lecture was then delivered by Captain P. P. Eckersley, Member, the subject being " Broadcasting by Electric Waves."

On the motion of the President, a vote of thanks to the lecturer was carried by acclamation and the meeting terminated at 7.15 p.m.

---

* Vol. 67, page 313. † *Ibid.*, page 291. ‡ *Ibid.*, page 293.

801ST ORDINARY MEETING, 13TH MARCH, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 27th February, 1930, were taken as read and were confirmed and signed.

Messrs. L. G. Bolton and D. P. Sayers were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the President reported that the members whose names appeared on the ballot lists had been duly elected and transferred.

The President announced that, during the month of February, 621 donations and subscriptions to the Benevolent Fund had been received, amounting to £270. A vote of thanks was accorded to the donors.

A paper by Messrs. H. A. Humphrey and D. M. Buist, Members, and J. W. Bansall, Associate Member, entitled " The Steam and Electric Power Plant of Imperial Chemical Industries, Ltd., at Billingham " (see page 1233), was read and discussed.

The meeting terminated at 7.55 p.m. with a vote of thanks to the authors, which was moved by the President and carried with acclamation.

802ND ORDINARY MEETING, 20TH MARCH, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 13th March, 1930, were taken as read and were confirmed and signed.

A paper by Mr. Bernard Leggett, M.R.C.S., L.R.C.P., Associate Member, entitled "The Medical and Surgical Applications of Electricity," was read and discussed.

The meeting terminated at 7.55 p.m. with a vote of thanks to the author, which was moved by the President and carried with acclamation.

803RD ORDINARY MEETING, 27TH MARCH, 1930.

Mr. P. V. Hunter, C.B.E., Vice-President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 20th March, 1930, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

A paper by Mr. H. H. Harrison, Member, entitled "Developments in Machine Telegraph Systems and Methods of Operation" (see page 1369), was read and discussed.

The meeting terminated at 8 p.m. with a vote of thanks to the author, which was moved by the Chairman and carried with acclamation.

804TH ORDINARY MEETING, 10TH APRIL, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 27th March, 1930, were taken as read and were confirmed and signed.

Messrs. R. S. Herbert and W. C. Kennett were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the President reported that the members whose names appeared on the lists had been duly elected and transferred.

The President announced that, during the month of March, 334 donations and subscriptions to the Benevolent Fund had been received, amounting to £170. A vote of thanks was accorded to the donors.

A paper by Messrs. S. W. Melsom, Member, A. N. Arman, B.Sc., and W. Bibby, B.Sc., Associate Members, entitled "Surge Investigations on Overhead Lines and Cable Systems" (see page 1476), was read and discussed.

The meeting terminated at 8 p.m. with a vote of thanks to the authors, which was moved by the President and carried with acclamation.

805TH ORDINARY MEETING, 1ST MAY, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 10th April, 1930, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

Messrs. D. J. Bolton, R. S. H. Boulding, O.B.E., and H. W. Gregory were appointed scrutineers for the ballot for the election of new members of Council.

The President announced that, during the month of April, 193 donations and subscriptions to the Benevolent Fund had been received, amounting to £102. A vote of thanks was accorded to the donors.

The President then presented the Faraday Medal for 1930 to Sir Ernest Rutherford, O.M., F.R.S.

Mr. R. H. Fowler, F.R.S., then delivered the Twenty-First Kelvin Lecture entitled "Some Recent Advances in the Electron Theory of Metals" (see page 1469).

A vote of thanks to the Lecturer, moved by Dr. W. H. Eccles, F.R.S., and seconded by Lieut.-Col. K. Edgcumbe, T.D., R.E.T.(Ret.), was carried with acclamation.

The meeting terminated at 7.30 p.m.

58TH ANNUAL GENERAL MEETING, 15TH MAY, 1930.

Col. Sir Thomas F. Purves, O.B.E., President, took the chair at 6 p.m.

The notice convening the meeting was taken as read. The minutes of the Ordinary Meeting held on the 1st May, 1930, were also taken as read and were confirmed and signed.

Messrs. G. R. Shepherd and H. C. Wilkinson were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the President reported that the members whose names appeared on the list (see page 1088) had been duly elected and transferred.

The Premiums (see page 795) which had been awarded by the Council for papers during the session were announced.

The President then summarized the Annual Report of the Council (see page 751) and moved its adoption.

Mr. J. O. Girdlestone seconded the motion.

Mr. F. W. Purse: I have one point of criticism. It is in regard to the membership, which is dealt with on the tenth page (see page 760) of the Report. We started the year with 1 959 full members, during the year we increased the total membership by 639, and we now have a membership of 14 200; and yet the deaths and resignations among the full members just balance the additions to that class. I cannot imagine an Institution of this character and size which during a period of 12 months cannot effectively increase its full membership. I think it must be due to lack of interest on the part of members who can transfer, and of others who are eligible and do not come forward, that we have not 2 000 full members. I raise the point in the hope that the technical Press will emphasize it and call attention to the fact that there are men who are not doing their best for the Institution and the profession.

The President: It is certainly a very important point. The present state of affairs is due entirely to the fact that proposals are not coming forward for full membership. I think it will be a good thing to turn over in our minds how we can best increase the number of full members, who, after all, are the most important section of the Institution.

Mr. W. C. P. Tapper: May I suggest that the Institution should keep a record of those who want copies of the Annual Report. We could register our names on a list, and copies would be sent to those who desire them. Then we shall have an opportunity of reading the Report before we get to the meeting and may be able to make useful suggestions.

The President: I would point out that in the notice convening the meeting, which was sent out on the 13th March, it is clearly stated that copies of the Report and Accounts can be obtained from the Secretary before the meeting. Nevertheless, I think that the suggestion of a list of members who desire to have copies of the Report is quite a practicable one. I will look into that with the Secretary and see if we can arrange machinery of that kind.

The resolution was then put to the meeting and carried unanimously.

Captain J. M. Donaldson: I should explain that I am speaking in place of the Hon. Treasurer who is undergoing medical treatment in Switzerland, and we are very glad to know that he is rapidly recovering and expects to be with us in August. I have to move "That the Statement of Accounts and Balance Sheet for the year ended 31st December, 1929, as presented be received and adopted." These Accounts you have in front of you, and I might also refer you to a very useful summary on the ninth page (see page 759) of the Report, which gives some of the vital points in considerable detail. Turning first of all to the Revenue Account, you will see on the left-hand side that the expenditure was some £34 356, as against £31 277 last year; in other words, we have spent a little over £3 000 more than we did last year. On the other hand, the income has increased by £1 689, which means, of course, that the surplus is a little less than last year. As a matter of fact, the surplus this year is £5 242, as against £6 041 in the preceding year. With regard to the increase of a little over £3 000 in expenditure, I would draw your attention to certain items which might be considered exceptional. One is an amount of £1 245 for the redecoration of this room. That, of course, will not happen again for many years. I think you will agree that the money was well spent. You will then see an item, "Structural Alterations £958 10s. 0d." That is, in the main, the cost of putting into use some rooms in the basement which were much needed. The other increases are not very great and are balanced by savings on some items. There is an increase of £620 in cost of management, which, of course, is natural with the increasing membership. More money has been spent on meetings because there have been more meetings. You will notice that the publication of the *Journal* actually cost £47 less than last year, although the volume was of larger size than in the preceding year. The explanation is that more money has been derived from advertisements. £144 has been saved on the rates of the building owing to the de-rating legislation. Travelling and legal expenses are less. The item of "interest on mortgage debt" now disappears because it has been cleared off. Another exceptional item of expenditure is on a bust of Faraday, which cost £37 and will not occur a second time. Another curious and interesting feature is that the cost of the Annual Dinner is £26 less than last year. On the Income side, we have about £1 250 more in subscriptions and £821 more in dividends and interest; there is a small falling off of about £100 in entrance fees. Publications show an increase of £59 and examination fees of £29, while there is a little drop in the subscriptions to *Science Abstracts*. On the other hand, of course, the item of £349 for the revenue from the Tothill Street property disappears; we have got rid of that property and I think that we have got out of it quite well. The Balance Sheet discloses a satisfactory state of things. You will notice how the Institution building and lease are dealt with. We paid for the building and lease some £73 000; I think that the lease has some 50 years to run; at the end of that period we shall have put by in the Depreciation Account £73 000, so that that asset will remain intact. We have transferred amounts from the Income and Expenditure Account to the General Fund and the Reserve Fund, and we have made further investments during the year, because we save, on an average, about £7 000 a year. The total of the securities held amounts to £97 000. That, of course, is the price at which they were purchased; their market value on 2nd May was £96 089; in other words, the depreciation is barely 1 per cent, which is not a serious matter. Taking the broad view of the situation, we have total assets of £186 343. The actual liabilities are £10 200, which is arrived at by adding up the second and the three following items on page 764; so that in point of fact we have a surplus of £176 143, which is about £8 000 better than the position last year. Those figures, I think, show that the prosperity of the Institution continues to be well maintained and that we are in a very strong financial position.

Mr. J. Harcourt Williams seconded the motion, which, there being no discussion, was put to the meeting by the President and unanimously carried.

Mr. T. E. Herbert: I have the honour to propose "That the best thanks of the Institution be accorded to the following officers for their valuable services during the past year: (*a*) the Hon. Secretaries of the Local Centres; (*b*) the Local Hon. Secretaries abroad; and (*c*) the Hon. Treasurer, Mr. E. Leete."

Mr. W. C. P. Tapper seconded the motion, which was carried unanimously.

Mr. S. Harcombe then moved "That Messrs. Allen, Attfield and Co. be appointed auditors for the year 1930-31." The motion was seconded by **Mr. Alan Williams** and was carried unanimously.

The meeting terminated at 6.30 p.m.

INSTITUTION NOTES.

Scholarships.

The following scholarships have been awarded for 1930–1931:—

Ferranti Scholarship (*Annual Value* £250; *tenable for* 2 *years*).

E. Wilkinson (Liverpool University).

Duddell Scholarship (*Annual Value* £150; *tenable for* 3 *years*).

T. R. Stretton (Cardiff Technical College).

David Hughes Scholarship (*Value* £100; *tenable for* 1 *year*).

H. A. Wainwright (Sheffield University).

Salomons Scholarship (*Value* £100; *tenable for* 1 *year*).

E. Bell (Armstrong College, Newcastle-on-Tyne).

War Thanksgiving Education and Research Fund (*No.* 1).

Grants of £50 each to:—

F. J. Clark (East London College).
Miss W. Hackett (Birmingham University).

Thorrowgood Scholarship (*Annual Value* £25; *tenable for* 2 *years*).

J. F. H. Tyler (Southern Railway Company).

Page Prize.

The above Prize for the session 1929–30 has been awarded to Mr. G. T. Winch for his thesis entitled "A Direct-Reading Photo-electric Photometer for the Commercial Measurement of Incandescent Electric Lamps" (see page 533).

Discussion on "Electric Lighting Fixtures and Modern Lighting."

A meeting of the Design and Industries Association will be held in the Institution Lecture Theatre on Tuesday, 25th November, at 8 p.m. (light refreshments 7.30 p.m.), when there will be a discussion on the above subject. The discussion will be opened by Mr. R. D. Best and Mr. Raymond McGrath.

Members of the Institution are cordially invited to the meeting and to take part in the discussion.

Model General Conditions for Contracts.

The Council desire again to call the attention of members to the work that has been done by the Institution in preparing and publishing model general conditions applicable to various classes of contracts.

In the past, a certain amount of friction and confusion has existed over general conditions of contract, buyers or consulting engineers using conditions which obviously put the contractor in a position where he was subject to disabilities which were hardly equitable; and, on the other hand, contractors putting forward conditions which relieved them of responsibilities which the purchaser had a right to expect them to assume.

It was for this reason that several years ago a committee was appointed by the Council, which included consulting engineers, manufacturers, contractors, representatives of municipal and company supply undertakings, etc., and, as a result, the document "Model Form of General Conditions, A (Home—With Erection)" was produced.

These conditions were intended for use in connection with central station contracts, and proved so useful that further sets of conditions have since been produced, applicable to specific classes of transactions (see list below).

In view of the large amount of work involved in producing these "Conditions," and the general agreement between all interests which they represent, the Council desire to call attention to the fact that they are "*recommended* by the Institution of Electrical Engineers," and to urge members of the Institution to make use of them as far as possible in their work, and to bring them to the attention of those who are outside the Institution membership.

List.

		Price (post free)
A.	Model Form of General Conditions (Home—With Erection)	2s. 2d.
B1.	Model Form of General Conditions (Export Delivery F.O.B.)	1s. 0d.
B2.	Model Form of General Conditions (Export, Including Complete Erection or Supervision of Erection)	1s. 0d.
C.	Model Form of General Conditions: Goods other than Cables (Home—Without Erection)	6d.
D.	Model Form of General Conditions: Cables (Home—Without Erection)	6d.
E.	Model Form of General Conditions: Cables (Home—With Erection)	(In preparation)

Copies can be obtained from the Institution or from Messrs. E. and F. N. Spon, Ltd., 57 Haymarket, London, S.W.

The Benevolent Fund.

An appeal for subscriptions, donations and legacies to the Benevolent Fund will be found on the last page of the cover of this issue of the *Journal.*

Discussions at Meetings.

The Council wish again to remind members that the remarks of speakers at the meetings should not be read from manuscript, the view being held that the presentation of remarks in this manner is contrary to the true spirit of a "discussion" and that contributions in manuscript should more appropriately be sent to the Secretary for publication in the *Journal* as "communicated remarks."

OBITUARY NOTICES.

GILBERT ARCHER was born in London on the 13th August, 1867, his father, Thomas Archer, being a well-known writer and an original member of the Savage Club. He was educated at Cowper Street School and studied electrical engineering at Finsbury Technical College under the late Prof. Silvanus Thompson. After a period of practical training with the Hammond Electricity Co., Brighton, he took up his first appointment in 1888, with the Brighton supply undertaking, when Mr. Arthur Wright was in control. In 1894 he went to Dublin as senior assistant to Mr. Mark Ruddle, of the Dublin Corporation Electricity Department, becoming chief assistant two years later. At that time the Dublin generating station was in Fleet Street, and the supply was single phase at 2 000 volts with house transformers and Callender bitumen cables. Ten years later, the late Mr. Robert Hammond installed the then new 3-phase 4-wire system of distribution and erected the generating station at Pigeon House Fort. Mr. Archer had a very extensive knowledge of 3-phase working in all its aspects, and more particularly on the distribution side. In 1918 he became deputy city electrical engineer of Dublin, a position which he held until his death. He was a tireless worker and was more a father than a chief to the members of his staff, by whom he was held in great affection and esteem. He was a man of many interests, and in a busy life found time for a vast amount of social and philanthropic work. The taking-over of the Dublin electricity undertaking in 1929 by the Free State Electricity Supply Board involved him in work which proved too much for his health, and he died in his office with tragic suddenness on the 13th December, 1929. A widow and two sons survive him. He was elected a Member of the Institution in 1927.

L. J. K.

THOMAS BAXENDALE died on the 6th December, 1929, in his 52nd year, after a comparatively short illness. He received his early education at the Bolton Church Institute, and later attended evening classes in engineering at the Technical Schools of Bolton and Manchester. The greater part of his career was spent in the service of the Manchester Corporation Electricity Department. He was appointed charge engineer at Stuart Street power station in 1902, in which year the supply of high-tension alternating current was inaugurated in Manchester. He became assistant resident and constructional engineer in 1913, and resident engineer in 1919. When Barton power station was laid down in 1923, he was transferred there, and, as resident engineer, he was in control during the difficult early years of the running of new plant which created a record for high thermal efficiency previously unattained in this country. In 1927 he became superintendent of power stations, a position he was destined to hold for but a short period before he became affected by heart trouble, which eventually brought about his death. A capable engineer, his disposition was kindly, and he was held in esteem and affection by his colleagues. In his humour there was often a vein of mild sarcasm, which, however, contained no barb and was largely discounted by an unfailing geniality. He was elected an Associate Member of the Institution in 1906 and a Member in 1922. He was also a member of the Committee of the North-Western Centre.

W. H. S.

SYDNEY WILLIAM BAYNES, a pioneer of the electrical industry, died on the 6th February, 1930, at the age of 69. His mechanical training was obtained as an apprentice to the late Mr. A. P. Lundberg, whom he followed into the service of Messrs. Crompton in 1878. While yet a mere boy, he showed such aptitude and keenness that his firm put him in charge of arc-lighting systems when these were first installed, and he had in most cases to teach the workmen the use of their plant. The charge of portable arc-lighting equipment took him into all parts of the kingdom and abroad, and on the recommendation of the head of the firm he took charge of similar plant at the Forth Bridge works. He was actually in charge for Messrs. Crompton when Swan's lamps were used in public for the first time at the Glasgow Exhibition in 1880. In 1888 he was appointed electrical engineer to the Bradford Corporation, the first municipal electricity undertaking in Great Britain, and in 1895 he entered the service of the Metropolitan Borough of St. Pancras, the first municipal electricity undertaking in London, as chief electrical engineer. He immediately set to work to double the pressure of supply, and in 1896 he was the first engineer to declare a 440-volt, 3-wire direct-current distribution with 220 volts to the middle wire. He was also one of the first supply engineers to foresee the immense possibilities of a cheap supply of electricity for manufacturing purposes. In 1903 he again led the way with a scheme for a 3-phase, 5 000-volt, 50-cycle alternating-current transmission to substations in remote parts of the area of supply, and in 1905 he was one of the first to adopt Parsons turbines to replace reciprocating engines. In 1912 he persuaded members of the Electricity Committee of the Borough Council to accompany him on a visit to Stockholm in order to investigate the Ljungström turbine, which was then being introduced to the electrical world. The first Brush-Ljungström turbine set (1 500 kW) made in England was installed in the St. Pancras power station. He was early interested in pulverized fuel, and St. Pancras was one of the first municipal undertakings to adopt this system of firing. Owing to ill health he retired from the service in December 1927, the Borough Council accepting his resignation with regret and placing on record their recognition and appreciation of the distinguished services he had rendered to the borough in connection with the development of the Council's electricity undertaking during his 32 years' service. Unfortunately his health remained indifferent, and he was unable in the remaining years of his life to secure the enjoyment that his strenuous efforts to cheapen the production of electrical energy had earned for him. He joined the Institution as an Associate in 1889, and became a Member in 1891.

J. T. B.

CHARLES ALBERT BLASCHECK was born in London on the 19th April, 1874, and died at Canterbury on the 26th November, 1929. In 1892, after two years as a pupil in the mechanical workshops of Messrs. Klein, Nuremberg, he entered the Frankfort works of Messrs. Schuckert and Co., leaving the following year to take up a course of training in electrical engineering at the Royal Technical College of Hanover. He left the College in 1895, and returned to England as an assistant with Messrs. Nicholson and Tyler. In 1896 he was engaged as an improver by the St. James and Pall Mall Electric Light Co., and from 1897 to 1899 he was assistant engineer in charge of a regular shift with the same company. From 1899 to 1902 he was chief assistant with the Norwich Electricity Co., and in 1902 he was appointed chief engineer of the Canterbury Corporation Electricity Works, a position which he held until his sudden death after an operation. His work and personality were greatly appreciated throughout his career. He was devoted to his work and will be missed by a wide circle of friends. He was elected an Associate Member of the Institution in 1902 and a Member in 1912.

A. D. B.

SEBASTIAN ZIANI DE FERRANTI, D.Sc., F.R.S., was born at Liverpool on the 9th April, 1864, and died at Zurich on the 13th January, 1930. He was educated at St. Augustine's College, Ramsgate, and for a short time he attended evening classes at University College, London, but his scientific knowledge was a matter of self-education, by reading books, by studying what others had done and by making his own experiments. His scientific bent was shown early in life; before he went to school he had constructed a battery and produced an arc light, and when he was at Ramsgate in 1878 at the age of 14 he constructed a dynamo. After he left college he had some small experience on the staff of Siemens Brothers and Co., but in 1882 he started in business for himself with Alfred Thomson and F. Ince as his partners, the latter being a solicitor by profession. This combination was formed to exploit the "Ferranti dynamo," a machine with flat coils having no iron in their cores, these being mounted on a hub and revolving between the poles of a ring of electromagnets. The magnets were relatively more powerful than those of its progenitor, the Siemens flat-coil alternator; the revolving coils were fixed to the supporting hub by a highly efficient mechanical method, and the disc thus formed was dynamically stiffened by its rotation. It achieved an instant success, having an output for its size greatly in advance of that of existing machines, but legislation had shut out all possibility of financing public supply undertakings, and other business was limited. Thus the new partnership was not successful, and after a period Ferranti started in business independently, being financed by Mr. Francis Ince. He turned his attention to the metering of electricity, and it was this that brought him in contact with the Grosvenor Gallery Electric Supply Corporation formed by Sir Coutts Lindsay and others to supply the Grosvenor Gallery and neighbourhood with electric light, using overhead mains. Ferranti had seen the Gaulard and Gibbs series transformer system which was at work at the Grosvenor Gallery installation, and he had also seen the Zipernowski transformers which were worked in parallel. He had made small transformers of a greatly improved mechanical construction, and had used them across constant-potential mains; thus when he learned of the trouble then being experienced with the regulation of the lamp pressure on the Gaulard-Gibbs system he was able to convince the directors of the Grosvenor Gallery of the superior advantages of his own system—comprising dynamo, transformer and meter—and at the age of 22 he was appointed engineer to the company. The success of the system which he installed decided the directors to put in hand the electrification of London, for which purpose Ferranti proposed to use the marine type of engine, which was known to work economically for long periods without stoppage. As it was then believed that alternators could not be run in parallel, units of 10 000 h.p. were decided upon, plans for a great central station at Deptford were completed, and construction was commenced. But meantime (1888) Parliament had revised the Electric Lighting Acts, and applications for provisional orders were made by various groups. The Board of Trade allotted so small an area to the Deptford undertaking that the construction of these large sets was stopped and smaller sets were installed. The plans for this central station were at the time entirely novel and opposed to all the existing ideas of other engineers, who sought to put the generating station as near the centre of the area to be supplied as possible. Ferranti conceived and put into operation the main principles on which all modern generation of electricity by steam power is based, viz. large generating stations near to ample supplies of cooling water, with facilities for bringing coal and removing ashes by water transport. Transmission to the point to be supplied was by means of high-pressure alternating current and transformers using high-pressure cables with impregnated paper insulation. After the completion and putting into operation of this generating station, Ferranti returned to electrical manufacturing, producing transformers, meters, rectifiers for arc-lamp lighting, oil breaker switches or fuses, and finally direct-driven steam generator sets. His modifications of the marine type of engine in which he endeavoured to improve the steam distribution by using slide valves moved by cams instead of eccentrics was not successful. Ferranti joined the Institution as a Member in 1891, and in the early days took part in the discussions at the meetings fairly frequently. He became a Member of Council in 1895 and President in 1910 and 1911. He was elected an Honorary Member in 1925. His presidential address was a new starting point for the electrical industry. He urged the universal application of electricity for all services.

Lighting, heating, motive power on every scale and for every purpose—whether domestic, factory or transport—was all to be electrical. He stressed the possibility of cheap supply under these conditions. From that date onwards, interrupted only by the War period, he pressed this ideal, and his reasoned argument, his enthusiasm in the propaganda, and the practical example which he set in his own home and elsewhere have been great factors in the remarkable expansion of the use of electricity since the War. His last appearance at the Institution was on the 19th December, 1929, less than a month before his death, when he opened the discussion* on Mr. T. G. N. Haldane's paper on an electrical heat pump. He will always be remembered in electrical work for these two great achievements, the production and transmission of electrical energy at high pressure and its distribution at low pressure, and the universal use of electricity for all purposes. Ferranti's activities were not confined to electrical work, for from 1895 onwards he worked on the gas turbine. He started his work with a patent for a combination of turbine, compressors and regenerators, working on the Carnot cycle, that is adiabatic compression and expansion—heat being taken in and given out by the working fluid (gas or steam) at constant pressure. He gradually realized, however, that this cycle—though theoretically the most efficient—leads to a small output from a given size of machine, and in 1902 he took out a patent for working on an isothermal expansion cycle, heat being supplied at stages during the expansion by the use of superheaters. This procedure has become standard practice in steam turbine work. Further, he developed the idea of abstracting some of the steam at successive stages for the purpose of raising the temperatures of the feed water to the temperature of the boiler, realizing that steam so abstracted after it had done some work was really operating at 100 per cent efficiency. This procedure again has passed into general practice. These studies and experimental work were preliminaries, so to speak, to work on the gas turbine, but enabled a great increase in efficiency to be realized, some particulars of which he gave in his presidential address already referred to, and also at the World Power Conference in 1924. He was eventually able to realize his project of burning gas at high pressure and temperature and expanding it through nozzles until it was cool enough to come in contact with the blades of the turbine, being still nearly red hot. But this cycle of operations calls for compression of the fuel gas and the air for combustion to the operating pressure, and even if liquid fuel is used the air has still to be compressed. The power required to do this, even with the most efficient types of pump, absorbs so large a part of the output of the turbine that the machine as a whole becomes uneconomic. From 1906 to 1930 Ferranti was occupied with the problem of increasing the speed of production and the quality of spun textile yarns. The process of twisting threads which had already been combed parallel was originally carried out by hand with the aid of a spinning wheel. It had been mechanized in two types, discontinuous spinning, that is a certain length at a time, by Hargreaves and Crompton, and the continuous process by Arkwright. The latter process enabled high speeds to be aimed at, but the limit had been reached due to unbalanced revolving parts, centrifugal forces acting on the thread as it was spun round at the bobbin, and irregular speeds owing to slipping of the bobbin driving bands. With his great power of analysis of a problem, and his equally great synthetic power—enabling him to integrate a new process leading from the same beginning to the same end—Ferranti removed the obstacles and greatly increased the speed of production, obtaining at the same time superior qualities of spun or twisted yarn. These experiments were still being carried out at the date of his death, and time only will show whether his new technique of this mechanical operation is a complete solution. Ferranti's retiring nature and modesty as to his own work were responsible for the slow recognition, except in specialist circles, of what he had done. He received the honorary degree of Doctor of Science of the University of Manchester in 1911; in 1924 he received the Faraday Medal of the Institution; and in 1927 he was elected a Fellow of the Royal Society. Ferranti married in 1888 Gertrude Ruth, second daughter of the late Mr. Francis Ince, whom he first met in 1882 at her father's house in Hampstead. He had three sons and four daughters. LL. B. A.

MICHAEL BIRT FIELD was born in London in May 1874, and died as the result of a street accident in February, 1930. He was educated at Highgate Grammar School and at Finsbury Technical College, where he studied under the late Professors Silvanus Thompson and John Perry, becoming personal assistant to the latter. In 1893 he entered the workshops of Messrs. Johnson and Phillips, and then joined Prof. Gisbert Kapp as assistant in 1894. The following year he went to Messrs. Brown, Boveri and Co., Baden, for whom he worked for three years in Switzerland and also in Spain. He joined the British Thomson-Houston Co. in London in 1898, but in 1900 went to Glasgow, where he was appointed chief electrical engineer to the Corporation Tramways and took charge of the newly-installed electrified system. During this period he read several papers before the Institution and was awarded a premium for one on "The Testing of Tramway Motors," which is a standard work on the subject. In 1903 he was appointed chief engineer to Messrs. Ferranti, of Hollinwood, where, after a visit to the United States for the purpose of studying American developments, he organized a switchgear department and prepared for the firm a catalogue on switchgear which was, in effect, an original and illuminating treatise on the subject. In 1911 he returned to Glasgow, being appointed chief engineer and general manager, and, afterwards, managing director to Messrs. Kelvin, Bottomley and Baird, the makers of Lord Kelvin's instruments. During the War period this firm was engaged in highly specialized work for the Admiralty, and Mr. Field was largely occupied in pioneer work on the design and construction of modern submarine periscopes. His attention had long been concentrated on navigational instruments, and in 1919 he delivered a lecture before the Institution on "The Navigational Magnetic Compass considered as an Instrument of Precision," which was awarded the Institution Premium. In the following year he contributed a paper on "Multiple-Unit Shunts for the Measurement of Very Heavy Currents" which was also awarded a Premium. Latterly his interests were concerned with aerial and marine navigational instruments, and before his death he was chiefly engaged on problems relating to acoustic depth-sounding. He was a man of outstanding ability as an engineer, a scientist, and a mathematician, and his untimely death is a very real loss to the profession and industry of engineering. He was elected an Associate of the Institution in 1894 and a Member in 1901.

W. W. L.

ALFRED ERNEST GREEN, who died on the 1st September, 1930, was born in 1872 and was educated at Oliver's Mathematical College, Portsmouth. He entered the naval service as an engineering cadet in 1887, and was trained at the Royal Naval Engineering College, Keyham, Devonport. After two years' service at sea he resigned his commission in the Royal Navy, and accepted the position of engineering instructor to the Chinese Navy. This appointment, which at first entailed looking into the progress of certain armament contracts that the Chinese Government had placed in this country, did not last very long. He was then for some time at the Maxim Nordenfelt Works, Erith, Kent, and afterwards on the staff of the British Thomson-Houston Co. In 1898 he became chief draughtsman in the late Sir James Clifton Robinson's offices at Stockton-on-Tees and Chiswick, London, but resigned in 1899 to join the staff of Messrs. Dick Kerr and Co., Preston, as chief engineer of the electrical erecting staff. Here he was responsible for the equipment of electric tramcars and electric rolling stock, for the installation of heavy generating machinery for power houses, etc., and for electric equipment for industrial purposes generally. When the company became merged in the English Electric Co. he retained his original position. He was elected a Member of the Institution in 1912.

J. C.

JOHN PUGH GREGORY, manager of the contract department of the British Thomson-Houston Co., died at Rugby on the 6th August, 1930. Born at Carnarvon in 1876, he was educated privately and at the High School, Oswestry. After serving an apprenticeship with Messrs. De Winton and Co., marine and general engineers, of Carnarvon, he left their works in 1896 to take up a position in the drawing office of Messrs. Ferranti, where he was for two years engaged upon work in connection with the steam side of electrical engineering. He subsequently studied at the Central Technical College, London. In 1899 he joined the testing department of the General Electric Co. of Schenectady, and later became one of their assistant engineers on power and mining work. After a year in America he was transferred to the London office of the company, resigning his position in 1901 to become assistant to the managing engineer at the British Thomson-Houston Co.'s new Rugby works. Shortly afterwards he was appointed manager of the power and lighting engineering department of the company, which ultimately became the present contract department. His duties brought him into contact with large numbers of electrical engineers all over Great Britain, many of whom became his personal friends. The British Electrical and Allied Manufacturers' Association owes much to his initiative and he was an active member of several of its committees. He was elected an Associate of the Institution in 1889 and became a Member in 1908.

FEARNSIDE IRVINE was born at Arbroath in 1856. He was educated at Glasgow University and received his early engineering training with Messrs. Alexander Shanks and Son, at Arbroath, Messrs. J. and G. Thomson, and Messrs. P. and W. McLellan, at Glasgow. His first appointments were those of assistant engineer to the Eastern Extension and Maintenance Cable Co., at Singapore, and assistant inspector of machinery for the Indian Government. Later, he acted as assistant engineer at Calcutta Water Works, engineer to the Cape Government Railways and Southern Mahratta Railways, and engineer to the African Gold Recovery Co., for whom he designed and equipped the first cyanide gold-recovery plant in the Transvaal. His appointment as engineer and manager at Johannesburg of several gold-mining companies, including the New Modderfontein Gold Mining Co., brought him the responsible task of equipping the Heriot, Henry Nourse, City and Suburban, Robinson, Paarl Central, Gold Reef, and New Modderfontein gold mines. From 1910 to 1913 he was engaged in re-equipping the Prestea Block A gold mines, Gold Coast Colony, the work including the design and installation of a complete modern power-station plant. He will be best remembered for his 30 years' association with the Capetown Tramways, Port Elizabeth Electric Tramways, and Lisbon Electric Tramways, for which systems he held the position of consulting engineer in London up to the time of his death on the 2nd November, 1929. He was elected a Member of the Institution in 1896.

ADMIRAL OF THE FLEET SIR HENRY BRADWARDINE JACKSON, R.N., G.C.B., K.C.V.O., F.R.S., was born at Barnsley in 1855. He served in the Zulu War in 1878 and was appointed to the torpedo school on the "Vernon" in 1879. Later his interest became concentrated upon the development of naval signalling. It is on record that in 1891 he urged the trial of Hertzian waves for short-range signalling; it is known that in 1895, when in command of the torpedo-school ship "Defiance," he successfully transmitted signals several hundred yards by reflector apparatus like that of Hertz, but with a Bose type of coherer at the receiving end and a tapper for causing decoherence after the receipt of each morse signal. Sir Oliver Lodge, by means of similar apparatus, had transmitted and received morse signals the preceding year but had made no attempt at application. Sir Henry Jackson was probably the first to make practical use of Hertzian waves, and he was certainly the father of marine wireless communication. In 1899 he assumed command of the "Vulcan" and in November 1901 reported to the Admiralty that by careful tuning he had established communication between two points in the Mediterranean separated by 134 miles. He had developed in 1900–01 a transmitter of his own design, in which a tuned primary circuit was coupled to a tuned aerial circuit by both condenser coupling and mutual inductance. The aerial was not earthed directly, but indirectly through the coupling condenser—a desirable arrangement on a ship. This transmitter operated on 600 m and 240 m; the inductances and condensers were carefully calculated with the aid of formulæ, and the capacities of typical forms of antenna were measured by laboratory methods. The fruits of a long series of measurements of the range of wireless stations over water and over various kinds of land formation and under miscellaneous atmospheric conditions were given in May, 1902, to the Royal Society, soon after he had gained the Fellowship. Until 1905 he was responsible for the whole development of naval signalling, and official equipment made excellent progress during his period of office. In 1905 he was appointed Third Sea Lord and Controller, and gradually lost touch with practical radio-telegraphy. At the beginning of the War he was appointed to the War Staff at the Admiralty and in May, 1915, became First Sea Lord. At the end of 1916 he left the Admiralty and was made an Admiral of the Fleet. In 1920 he resumed his active participation in wireless by accepting the Chairmanship of the Radio Research Board. In 1924 he acted as Chairman of the Transatlantic Telephony Committee. His success in these important offices was largely due to his receptiveness for new ideas. This modernity was strikingly shown by the way he followed up the amateur short-wave movement from 1922 onwards. He died on the 14th December, 1929. In his work for wireless he was conspicuous for his unselfish, far-seeing, scientific efficiency and his avoidance of controversies about priority. He was elected an Associate of the Institution in 1883 and a Member in 1902. W. H. E.

WALTER JUDD was born in October, 1852, and died at Bracknell, Berkshire, on the 20th February, 1930. He entered the service of the Eastern Extension Australasia and China Telegraph Co. in July, 1870, being rapidly promoted to the position of local manager in 1874. He served in this capacity at all the principal stations of the company, including Singapore, Shanghai, Hong-Kong and Penang, and in 1886 he was appointed manager in the Far East. In April, 1897, he became assistant electrician-in-chief in London to the Eastern Telegraph Co. and its associated group of companies, succeeding Mr. H. A. C. Saunders as electrician-in-chief in January, 1905, upon the latter's retirement. Mr. Judd's association with the electrical department of the associated companies signalized the beginning of reorganization and development of improved methods of working, and to his marked ability, untiring energy, and devotion to the companies' interests great advances were due. The primitive methods which survived from earlier days were soon modified in accordance with the more up-to-date principles upon which the present system has developed. The use of more delicate and intricate apparatus, for the design of which he was responsible, permitted the great increase in traffic to be carried. A vast amount of research in the manufacture and balancing of cables was also necessary in order that full advantage might be taken of the benefits accruing from the improved apparatus. The combined results of the investigations carried out under his direction laid the foundation for the present-day methods of working, which have practically revolutionized the art of cable and submarine telegraphy, and with which his name will always be associated. During the War a great strain was thrown upon Mr. Judd and the technical department of the companies, by the necessity for maintaining the all-important cable communications, and for assisting the Government by meeting their many requirements for urgent strategic connections in all parts of the world. With the declaration of the Armistice Mr. Judd intimated his retirement, which took effect in March, 1919, after he had completed 49 years of cable service. He possessed a strong personality, which imbued his staff with confidence and a desire to emulate their leader. He became an Associate of the Institution in 1875, and a Member in 1877. He served on the Council for many years between 1905 and 1919, including a period of office as Vice-President from 1912 to 1915. J. C. B.

JOHN WILLIAM LIEB died at New Rochelle, New York, on the 1st November, 1929, at the age of 69. Born in 1860, he received his early training in electrical engineering at the Stevens Institute of Technology, New Jersey. In 1881 he joined the staff of the Edison Electric Light Co. of New York as a draughtsman, and was soon afterwards engaged in experimental work under Mr. Thomas Edison. In the following year he was appointed chief electrician of the company, and in 1883 chief engineer and technical director of the Italian Edison Co., Milan. He returned to New York in 1893 as a vice-president and general manager of the Edison Electric Illuminating Co. and a vice-president and associate general manager of the newly-formed New York Edison Co., eventually becoming general manager of the latter. In 1928, after 25 years' tenure of these positions, he retired from active service and became senior vice-president of the companies. He was elected a Member of the Institution in 1911, and was also a past-president of the American Institute of Electrical Engineers.

Sir BENJAMIN LONGBOTTOM died at his home at Totteridge on the 1st May, 1930, in his 54th year. Educated at Heath Grammar School, he received his training in electrical engineering at Ilkley College, and was an articled pupil with Messrs. Andrews and Preece, Ltd., Bradford, from 1892 to 1895. He was subsequently with the Phœnix Dynamo Co., Bradford, as an improver, and in May, 1898, he became superintendent engineer in charge of outside power work for the General Electric Co., Manchester. During his last 15 months with the firm he was assistant works manager. At the age of 24 he became general manager and engineer of Electromotors, Ltd. (now Laurence, Scott and Electromotors, Ltd.), a company which owed much of its subsequent success to his organizing ability. Under his leadership the firm began to manufacture in bulk a complete range of component parts suitable for d.c. motors of from $\frac{1}{2}$ to 20 h.p.; this was an entire departure from standard practice and enabled new machines to be assembled and delivered to order within a short and definite period of time. The immediate success of this policy was a tribute to his energy and foresight, and the long-continued prosperity of the firm bears witness to his consistent enthusiasm for good work. During the War he rendered valuable service to the Electrical Advisory Committee appointed by the Ministry of Munitions, and the Electrical Trades Committee. For some years he was a member of the Council of the British Electrical and Allied Manufacturers' Association, being chairman of that body from 1922 to 1925. During this period the Association organized one of the most successful exhibits in the Wembley Exhibition. His keen interest in public affairs found an outlet in the activity which he displayed on the board of the Manchester Chamber of Commerce. He was knighted in 1925. While still remaining manager of Electromotors, Ltd., he was also vice-chairman of Richard Johnson, Clapham and Morris, Ltd., and a director of Lo-Thermo Patents, Ltd. He was chairman of the executive committee of the World Power Conference. His death, occurring soon after that of Dr. S. Z. de Ferranti, was another severe loss to the industry as well as to a wide circle of friends to whom he had endeared himself by his genial and generous nature. He joined the Institution as an Associate Member in 1904, became a Member in 1909 and served on the Council from 1924 to 1927. C. R.

COLONEL EDWARD DONALD MALCOLM, C.B., R.E., one of the two surviving original members of the Society of Telegraph Engineers, now the Institution of Electrical Engineers, died in March, 1930, in his 93rd year. Born in 1837, he entered the Royal Academy, Woolwich, at the age of 14 and left to join the Royal Engineers in 1854. Returning to England after a distinguished military career, during the course of which he served in the Crimean War and took part in the suppression of the Indian Mutiny, he was appointed Inspector of Submarine Mining Defences at the War Office. He later took up the position of Officer Commanding the Royal Engineers on the staff in Scotland. On leaving the Army he became Commissioner Engineer in regard to piers and harbours in the crofting districts of the Highlands, for several years administering the Highlands and Islands Act of 1891. He was one of the three Commissioners appointed to rectify the boundaries of the counties and parishes in Scotland, a piece of work which owed much of its success to his tact, ingenuity, and intimate knowledge of local conditions. M. M.

ROLAND MARSHALL, who died on the 12th June, 1929, at the age of 56, received his early training at the Finsbury Technical College. He was for four years a pupil in the works of Messrs. Siemens Brothers, and was subsequently employed by them for many years as an engineer in charge of submarine cable laying and maintenance work, and also in carrying out contracts in connection with the laying of cables and the installation of plant for various electricity supply undertakings, including those at Londonderry, Hull and Ayr. He was also largely responsible for the erection of the overhead and station equipment for the Blackburn Corporation Tramways. He was then for three years chief assistant engineer at the Ayr Corporation Electricity Works, becoming chief engineer and manager in 1903. During his 23 years' service with the Corporation he was responsible for important additions to the generating plant and extensions of the mains. He was in recent years actively concerned in the project for harnessing the water power of Loch Doon in connection with the Ayr electricity supply. Outside his profession his main interests lay in music, golf and fishing. His qualities of head and heart endeared him to all with whom he came in contact. He joined the Institution as an Associate in 1898, and was elected an Associate Member in 1902 and a Member in 1909.

WILLIAM HENRY MAYSTON was born in 1885, and died in London on the 15th February, 1930. He was educated at the Brighton Grammar School and the Brighton Technical College. In 1899 he entered the service of the Eastern Telegraph Co. as a probationer, and in the course of the usual training at the company's school showed special aptitude for the technical and electrical side. He was subsequently appointed to the electrical staff at Porthcurnow, and thereafter served in this branch of the service from the rank of junior to the responsible position of senior electrician at the company's main line stations in the Mediterranean, Red Sea, on the east coast of Africa, in South Africa, and at Rodriguez and Seychelles, with intermittent periods in the electrical department at the company's head office in London. He was elected an Associate Member of the Institution in 1908 and a Member in 1921. J. C. B.

FRANCIS JOHN MUDFORD was born at Tiverton, Devonshire, in 1857, and died on the 13th November, 1929. He had a natural aptitude for the study and practical application of physical science, and from his school at Tiverton, where at one time he taught this subject, he gained a scholarship at the Royal College of Science, South Kensington. This was about the time when the telephone, the dynamo, and the incandescent lamp were invented, and when the Institution of Electrical Engineers was the Society of Telegraph Engineers. He turned his attention to electrical engineering, and after leaving the College became technical adviser to Messrs. Paterson and Cooper, one of the pioneer firms of the industry. Here he took part in the manufacture of the first (Gower Bell) telephones for the Post Office, and of the first ammeter, when this instrument for the direct measurement of current had been invented by Ayrton and Perry. Later, when in business on his own account, his exceptionally wide knowledge led him to undertake a variety of electrical work, much of it experimental, and at this he was generally successful and always happy. He treasured his contacts with Lord Kelvin, Professors Ayrton, Perry, Guthrie and Silvanus Thompson, and with his closer friend, S. A. Varley. He joined the Institution as an Associate in 1881 and became a Member in 1891. W. T.

GEORGE ARMSTRONG PEARSON, who died on the 20th October, 1929, was born in 1874 and was educated at Great Yarmouth College, the School of Electrical Engineering, Hanover Square, and the Finsbury Technical College. After two years' practical work, first with Messrs. Crompton and subsequently with the

British Insulated Wire Co., he became a charge engineer in the service of Messrs. Hartley and Co., Bradford. In 1897 he joined Messrs. Pearson and Co., of Bath, but after four years—during two of which he conducted evening classes in electrical engineering at the Bath Technical School—he decided to devote the whole of his time to lecturing and his practice as a consulting engineer. He became head of the department of electrical engineering at Bolton Technical Institute in 1901, and later occupied similar positions successively at Hull, Loughborough and Halifax Technical Colleges. His sportsmanship and genial sense of humour made him popular with his students and his colleagues. He was elected an Associate of the Institution in 1896, an Associate Member in 1899, and a Member in 1913. A. H. L.

PERCIVAL JOHN PRINGLE died in Switzerland on the 10th June, 1930, in his 60th year, while returning from Australia to England on a business visit. Born in 1870, after a short course of electrical training at the School of Electrical Engineering in Hanover Square he became a pupil of Messrs. Dubs and Co., Glasgow, and was subsequently engaged in research work with Prof. G. Forbes. In 1890 he joined the staff of Messrs. Drake and Gorham and was rapidly promoted to the position of manager of their Birmingham works. Later, in the service of the Brush Electrical Engineering Co., he was in charge of the erection of the Wandsworth central station and of extension plants for the Sheffield, Huddersfield, Leicester, and Watford undertakings. As a resident engineer in the employ of Messrs. Kincaid, Waller, Manville and Dawson he supervised the whole of the power scheme of the Midland Electric Power Corporation. He designed and patented the Pringle and Kent surface contact system of electric traction. In 1903 he took up the position of electrical engineer and tramways manager to the Burton-on-Trent Corporation. He resigned this position in 1911 to go to Australia as general manager and chief engineer of the Electric Supply Co. of Victoria, Ltd. As arbitrator in connection with tramway labour disputes he figured prominently in Australian public affairs. He was elected an Associate of the Institution in 1895, an Associate Member in 1899, and a Member in 1902.

ANDREW FREDERICK ROCK died at Rhos-on-Sea on the 29th March, 1930, at the age of 70. In 1872 he became a telegraph clerk in the employ of the North Staffordshire Railway Co. at Stoke-on-Trent, and after four years' service he was appointed an inspector in charge of the construction and maintenance of telegraph systems. He obtained a knowledge of the theoretical side of electrical engineering by attending technical classes in his spare time at Hanley and Stoke. In 1886 he took up the position of chief assistant to the late Mr. John Neale, whom he succeeded as electrical engineer and telegraph superintendent of the company in 1902. From that year until his retirement in 1924 he was in charge of the whole of the electrical equipment of the North Staffordshire Railway. During his period of service the personnel of his department increased from 40 to about 300, and the line also became the North Staffordshire Section, London, Midland and Scottish Railway. He was for eight years honorary secretary to the Railway Electrical and Telegraph Engineers Conference, and was also a member of the Council of the Institution of Railway Signal Engineers. He joined the Institution of Electrical Engineers as an Associate Member in 1902, and became a Member in 1908.

GUIDO SEMENZA was born in London on the 19th December, 1868, and died at Milan on the 7th November, 1929. He went to Italy at an early age and in 1893 graduated as an engineer from the Polytechnic High School of Milan, gaining an electrical engineering diploma at the Montefiore Electrotechnical Institute at Liége a year later. He devised and put into operation the first hydro-electric plant at Paderno for the Italian Edison Co. of Milan, this work being carried out shortly after the famous experimental three-phase transmission between Lauffen and Frankfort in 1891, and the first large-scale transmission system between Tivoli and Rome in 1892. Power was transmitted from the Paderno station at 13 600 volts, three-phase, and as no machinery which could work at such a pressure was then available, Semenza had himself to design suitable equipment. This pioneer work made his name famous in the electrical world, and his advice on similar problems of power supply was sought both in Italy and abroad. He also made a special study of electric communication and traction problems, and the Italian Government and many public and private bodies obtained the advantage of his experience. In addition to his engineering abilities he was a man of deep scientific insight and was also keenly interested in philosophy and music. He published many papers on important electrical engineering problems, and in 1924 he delivered the 15th Kelvin Lecture before the Institution, taking as his subject Kelvin's Conductor Law and its adaptation to the problems of the generation and distribution of electrical energy. As president of the Italian Electrotechnical Association he did much to extend its influence and to link it up with similar associations in other countries. From 1923 to 1927 he was president of the International Electrotechnical Commission, and during this period presided over the New York and Bellagio General Meetings of the Commission. In 1929 he was awarded the Faraday Medal of the Institution, and the same year he was the recipient of a presentation from the Italian Electrotechnical Association. Owing to failing health the last years of his life were devoted to literary rather than to scientific work. His death means to the electrical world the loss of a far-seeing pioneer and powerful driving force, and to Italy the passing of one of her most devoted citizens. He was elected a Foreign Member of the Institution in 1900, became a Member in 1903, and was for many years Local Hon. Secretary for Italy. L. L.

LIEUT.-COLONEL ALEXANDER SINCLAIR, T.D., was born at Aberdeen in 1861, and died at Swansea on the 18th February, 1930. He was educated privately and abroad, and he studied mechanical and electrical engineering in London. Under Messrs. Siemens Brothers of Charlton he took part in the manufacture and laying (in the " Faraday ") of the Mackay-Bennett cable to America, and he also served with Messrs. Goolden and

Trotter, of London. In 1885 he was appointed works manager to Messrs. Vivian and Sons, Swansea, from which position he retired in 1925. At these works he organized a complete and successful plant for the manufacture of copper shell bands. In 1897 he was elected a Councillor to the Swansea Corporation and was a member of the Council continuously up to the time of his death. During his 32 years on the Council he was twice elected an Alderman and was Mayor of the Borough for the year 1919–20. He was also a Justice of the Peace for the County Borough of Swansea. Whilst he rendered valuable service by his membership of several other important committees of the Corporation, it was as Chairman of the Electricity Committee over a period of 26 years that he served most admirably the interests of the town of Swansea, for during this time he played a great part in the development of the electricity undertaking. During the War period he was a member, and for a time Chairman, of the Local Tribunal; he was also Chairman of the Local Food Committee, and of the Road Transport Board for the West Glamorgan Area. He served on the District Joint Board for the Electricity Supply Industry in the South Wales and Monmouthshire area and was Chairman of that body for several years. He was for a considerable period a member of the Council of the Incorporated Municipal Electrical Association. In 1885 he joined the 1st Glamorgan Rifle Volunteers as a Lieutenant, and was later Second and temporarily in Command. When this regiment was disbanded in 1904 he transferred to the 3rd Glamorgan Rifle Volunteers, and after some years as Second-in-Command he retired in 1912, owing to ill health, with the rank of Major and Honorary Lieut.-Colonel. He was elected a Member of the Institution in 1887. J. W. B.

DANE SINCLAIR, one of the rapidly diminishing band of British telephone pioneers, died on the 6th May, 1930, at the age of 78. He was born in Caithness on the 6th June, 1852, and joined the telegraph department of the North British Railway in 1872. In 1875 he was selected to go to Japan in the capacity of inspector of telegraphs for the Japanese Government. On his return to this country, after four years in Japan, he was for a time in charge of the telegraph department of the Dundee and Arbroath Joint Railway, and in 1882 he became engineer to the National Telephone Co., in the Glasgow district. This period of his career was marked by a number of inventions connected with telephony. When the three principal telephone companies were amalgamated, forming the new National Telephone Co., he furnished the directors with a report on the system. His report formed the basis of an entire reorganization, and he was appointed London manager. In June, 1892, he became engineer-in-chief of the National Telephone Co., which position he continued to hold until 1902. He was the first British telephone engineer to apply automatic switching mechanism to public telephone service. This was carried out at Coatbridge, where an automatic switchboard of his own invention linked up a small number of subscribers to a distant main exchange over a single-junction circuit. An example of this switchboard is deposited in the Institution Museum. In 1902 he severed his connection with the National Telephone Co. at the invitation of the directors of the (then) British Insulated and Helsby Cables, Ltd., to become general manager of that company. He later became a director and, finally, chairman of the company, which expanded rapidly under his guidance. When the Automatic Telephone Manufacturing Co., Ltd., was formed in 1911 he was appointed managing director, a position which he held in addition to that of general manager of British Insulated and Helsby Cables, Ltd. He was also a director of the Associated Telephone and Telegraph Co., the International Automatic Telephone Co., the Midland Electric Corporation for Power Distribution, Ltd., Enfield Cable Works, Ltd., and the Electric Supply Company of Victoria, Ltd. He was a man of sterling character and, in spite of his heavy business cares, took a benevolent interest in the welfare of the large staffs which he controlled. His leisure hours were devoted to contemplative reading, his tastes being those of the literary student. He joined the Institution as an Associate in 1883, became a Member in 1893 and served on the Council from 1896 to 1898. H. H. H.

JAMES WILLIAM SPEIGHT died at Ormskirk on the 26th May, 1930, in his 65th year. In 1889 he joined the Bradford Corporation Electricity Department, remaining on the staff until 1896, when he was appointed outside superintendent in the Blackpool Corporation Electricity Department, later becoming deputy borough electrical and tramway engineer. In 1902 he entered into partnership as a consulting electrical engineer with Mr. Quin in London, and during a period of four years he laid down electric tramway systems at Dundee, Broughty Ferry, and Shipley (Yorks). He also supervised the erection of the electricity works at West Bromwich and was concerned with the Ilkley and Great Harwood undertakings. From 1906 to 1914 he lived at St. Annes, being largely responsible during that period for the Bispham-Norbreck electricity scheme for the Bispham Urban District Council. He was managing director and consulting engineer to the Penrith Electric Supply Co. from its formation in 1908 until his death, and held similar positions with the Ormskirk undertaking from 1912 until his retirement from the company in 1929, when the Lancashire Electric Power Co. purchased a controlling interest in its shares. He joined the Institution as an Associate in 1896 and became a Member in 1898. J. H. H.

ALAN ARCHIBALD CAMPBELL SWINTON, F.R.S., was born on the 18th October, 1863, and died on the 19th February, 1930. His death means a heavy loss to scientific research, for he carried out numerous valuable investigations, particularly in connection with X-rays and radio communication. He was the third son of Archibald Campbell Swinton, of Kimmerghame, Berwickshire, a professor of civil law in the University of Edinburgh from 1842 to 1862. Even in childhood Mr. Alan Campbell Swinton showed an interest in engineering, as is evidenced by an oil painting of him at the age of nine with a steam-engine in his hand which was exhibited at the Royal Scottish Academy Exhibition in 1872. At his first school—Cargilfield, Edinburgh—he was allowed to cultivate his scientific talent. He became a practised photographer, and gave exhibitions with a magic lantern for the entertainment of his schoolfellows. His dislike of games and the humdrum methods adopted in the teaching of the classics made life distasteful to him at Fettes College, the public school which he entered in 1878. He found a solace there, however, in his work in the carpenter's shop. In 1879, some two years after the invention of the telephone, he read an account of the instrument written by Prof. Dolbear. Although he was only fifteen, within a short time he had constructed an efficient pair of telephones unaided, a task which would have presented some difficulty even to a trained scientific worker. After two years at Fettes he was sent abroad for a short period. He studied mathematics and French at Havre, and was greatly delighted by the collection of electrical apparatus which he saw at the Paris Exhibition in 1881. Returning to England, he was in the following year apprenticed to Messrs. W. G. Armstrong, Mitchell and Co. at their Elswick works. Here he took part in the work of equipping a battleship with electric gun-firing control. At the close of his period of apprenticeship in 1887 he became an electrical contractor and consulting engineer in London. He had previously published a book, "The Principles and Practice of Electric Lighting," and his work now included the installation of electric light in many large town and country houses. His connection with X-rays began in January, 1896, when—inspired by a newspaper account of Prof. W. K. Röntgen's discovery—he employed a Crookes tube to obtain the first X-ray shadow photograph ever produced in this country, a photograph of the bones in his own hand. With Sir Charles Parsons he heated a diamond in a vacuum by means of cathode rays. The diamond was converted into coke at a temperature of 1890° C., at the same time undergoing a considerable increase in size. From 1904 onwards he devoted his entire attention to consulting work and became particularly interested in radio engineering. He introduced the Marchese Marconi to Sir William Preece on the occasion of the first visit of the former to this country, and radio telegraphy made rapid strides shortly afterwards. In 1924 Mr. Campbell Swinton became a member of the Broadcasting Board. He was a director of the Parsons Marine Steam Turbine Co., Ltd., and was connected with the development of the Parsons turbine and the first turbine-driven boat, the "Turbinia." He was also a director of Crompton, Parkinson, Ltd., of W. T. Henley's Telegraph Works, Ltd., and of Ricardo and Co., Worthing. In 1915 he was elected a Fellow of the Royal Society, and twice served on the council of that body. He was one of the managers of the Royal Institution for the period 1912–15, and had been president both of the Röntgen Society and the Radio Society of Great Britain. For periods of varying length he had been a member of the general board and of the executive committee of the National Physical Laboratory, and vice-president and chairman of the council of the Royal Society of Arts. Throughout his life he was a great believer in self-education, and he considered the passing of advanced examinations to be a waste of time. In his opinion his own success was due to the cultivation of scientific friends, and attendance at lectures such as those delivered at the Royal Institution and the Royal Society of Arts. At his home (he was unmarried) he showed great hospitality, delighting to entertain his guests with demonstrations of the most recent achievements in radio communication and with a collection of photographs which he had taken of eminent scientists. He joined the Institution as an Associate in 1886, was elected a Member in 1890 and was a Vice-President during the years 1921–25. A. R.

  Null method of testing instrument transformers. (D), 908.
  Precision testing of current transformers. (D), 908.
Honaman, R. K. Interference between power and communication circuits. (D), 1230.
Honours conferred on members. 752.
Hooper, J. F. W. Elected Member of Council. 1086.
Hopkinson (John) Premium awarded to L. C. Grant. 795.
——, presentation of oil painting of. 199, 753.
Horn, T. L. Water penetration effects in lead-sheathed cables. (D), 1083.
Horner, F. W. L. Salomons Scholarship awarded to. 83, 755.
Horsley, W. D. Voltage control of large alternators. (D), 787.
Horton, C. E. Developments in direction-finding apparatus. (D), 1070.
Hoseason, D. B. Measurement of noise of machinery. (D), 126, 784.
Houses, " all-electric," progress with. C. G. M. New, (p), 151.
Howard, C. Heating of buildings by thermal storage. (D), 688.
Howarth, O.
  Heating of buildings by thermal storage. (D), 690.
  Instrument transformers. (D), 728.
  Metering arrangements for the " grid." (D), 1503.
  Voltage control of large alternators. (D), 790.
Howell, A. Plant of Imperial Chemical Industries at Billingham. (D), 1280.
Hughes (David) Scholarship, award of:
  1929. P. F. Soper. 83, 755.
  1930. H. A. Wainwright. 1530.
Hughes, E.
  Determination of temperature-rise of electrical machines from short heating tests. (P), 932.
  Heating tests on electrical machines. (P), 912.

Hughes, L. E. C.
  Measurement of noise of machinery. (d), 127.
  Students' Premium awarded to. 941.
Humphrey, H. A., Buist, D. M., and Bansall, J. W.
  Paris Premium awarded to. 795.
  Plant of Imperial Chemical Industries at Billingham. (p), 1233.
Hunt, F. O. Measurement of noise of machinery. (d), 780.
Huntley, R. J. Plant of Imperial Chemical Industries at Billingham. (d), 1287.
Hydro-electric development, the Serra. R. W. H. Couzens, (p), 1291.
Hysteresis measurements on straight bars and strips. C. E. Webb and L. H. Ford, (p), 1018.

I.

Ignition systems for automobiles, progress in. S. P. Smith, (p), 164.
Illumination. (*Also see* Lamp *and* Lighting.)
—— Congress, International, 1931, announcement of. 202.
——, uniform, over large areas, production of. H. R. S. McWhirter, (p), 1012.
Impedance, mechanical, measuring. E. Mallett and R. C. G. Williams, (p), 560.
—— of distributed resistance. R. S. J. Spilsbury and A. H. M. Arnold, (p), 896.
—— of 3-phase overhead lines. P. D. Morgan and S. Whitehead, (p), 367; (d), 778.
Imperial Chemical Industries, plant of, at Billingham. H. A. Humphrey, D. M. Buist and J. W. Bansall, (p), 1233; (d), 1276.
Industries Association, Design and, meeting of. 1530.
Industry, electrical, in Great Britain, organization of. 1368.
Informal Meetings. (*See* Meetings, Informal.)
Installation accessories, progress in. C. G. M. New, (p), 148.
Institution building, Council's report on use of. 753.
—— Notes. (*See* Notes.)
——, organization of. 760.
—— Premium awarded to H. H. Harrison. 795.
—— representatives on other bodies. 202, 761.
——, work of. Sir Thomas Purves, (p), 1.
Instrument for surge measurements. S. W. Melsom, A. N. Arman and W. Bibby, (p), 1477.
—— Section, Meter and. (*See* Meter.)
—— transformers. J. G. Wellings and C. G. Mayo, (p), 704; (d), 719.
—— transformers, null method of testing. G. F. Shotter, (p), 873; (d), 906.
Insulation. (*Also see* Dielectric.)
—— in h.t. machines. P. P. Eckersley and N. Ashbridge, (p), 1156.
Insulators in naval communications. G. Shearing and J. W. S. Dorling, (p), 251.
——, porcelain, for overhead lines, design of. S. W. Melsom, A. N. Arman and W. Bibby, (p), 1483.
Interference between power and communication circuits (E.R.A. Report). (p), 587; (d), 1230, P. D. Morgan and S. Whitehead, (p), 380; Sir Thomas Purves, (p), 495.
International Conference, fifth, on large electric systems. 314, 756.
—— Illumination Congress, 1931, announcement of. 202.
—— organizations, Institution and. 756.
Irvine, F. Obituary notice. 1534.
Italy, Local Hon. Secretary for, L. Emanueli appointed. 314, 756.

J.

Jackson, Sir Henry.
  Obituary notice. 1534.
  Vote of condolence on death of. 521.
Jackson, J. M. Measurement of noise of machinery. (d), 785.
Jackson, J. W. Voltage control of large alternators. (d), 787.
Jackson, S. B. Metering arrangements for the "grid." (d), 1505.
Jackson, W.
  High-frequency resistance measurement. (p), 296.
  Voltage control of large alternators. (d), 789.
Jakeman, R. G. Voltage control of large alternators. (d), 335.
Jarvis, A. P., and Cramp, W. Analysis of carbon arc phenomena. (p), 1301.
Jeans, Sir James H. Speaking at Annual Dinner, 1930. 652.
Jefferson, J. L. Measurement of noise of machinery. (d), 782.
Jet-wave rectifier. J. Hartmann, (p), 945; (d), 969.
Jewsbury, S. S. Heating of buildings by thermal storage. (d), 686, 691.
Jockel, L. M.
  Breaking performance of high-power switchgear. (d), 1118.
  Low-temperature carbonization of fuel. (d), 234.
Jones, I. Protection of 3-phase lines and feeders. (d), 847.
Judd, W. Obituary notice. 1535.
Juhlin, G. A.
  Measurement of noise of machinery. (d), 785.
  Voltage control of large alternators. (d), 788.

K.

Kahn, M. L. Voltage control of large alternators. (d), 336.
Kapp, Dr. G., letter from Lord Kelvin to. 796, 1368.
Kapp, R. O. Protection of 3-phase lines and feeders. (d), 827.
Kelly, A. C. Diesel engine applied to railway traction. (d), 504.
Kelvin Lecture, 21st. R. H. Fowler, (p), 1469.
—— Medal awarded to A. Blondel. 83.
—— Premium awarded to T. G. N. Haldane. 795.
Kelvin's letter to Dr. Kapp. 796, 1368.
Kemp, P. Heating of buildings by thermal storage. (d), 678.
Kennedy-Purvis, C. E. Address as chairman of Wireless Section. 16.
Kernick, T. R. Protection of 3-phase lines and feeders. (d), 848.
King, A. J., and Churcher, B. A. G.
  Ayrton Premium awarded to. 795.
  Measurement of noise of machinery. (p), 97; (d), 129, 781, 783, 786.
Kinman, T. H. Measuring performance of radio receivers. (d), 491.
Kitchen, H. Developments in machine telegraph systems. (d), 1458.
Klydonograph and lightning surges. H. Norinder, (p), 525.
—— for surge measurements. S. W. Melsom, A. N. Arman and W. Bibby, (p), 1477.
Knowlson, J. McK. Measurement of noise of machinery. (d), 780.
Kuyser, J. A. Voltage control of large alternators. (d), 331.

L.

Lamb, H. C. Pulverized fuel in power stations. (d), 511.
Lamp. (*Also see* Illumination *and* Lighting.)
——, incandescent electric, jubilee of. 757.
——, incandescent electric, photo-electric photometer for measurement of. G. T. Winch, (p), 533.
Lander, C. H. Low-temperature carbonization of fuel. (d), 230.

Lane, F. J. Protection of 3-phase lines and feeders. (d), 824.
Langley, A. H. Heating of buildings by thermal storage. (d), 693.
Lawson, R. J. Address as chairman of Dundee Sub-Centre. 69.
Lawson, W.
  Frequency variations in watt-hour meters. (d), 1034.
  Rotor bearings of electricity meters. (d) 1522.
Leach, H. L. Bequest under will of. 757, 1526.
Leaves from engineer's notebook. H. W. Walker, (p), 73.
Leben, H. Protection of 3-phase lines and feeders. (d), 844.
Lecture, Faraday. (*See* Faraday Lecture.)
——, Kelvin. (*See* Kelvin Lecture.)
Lee, A. G. Developments in machine telegraph systems. (d), 1455.
Leeson, B. H.
  Breaking performance of high-power switchgear. (d), 1118.
  Protection of 3-phase lines and feeders. (d), 843.
Leeson, B. H., and Clothier, H. W. Protection of 3-phase lines and feeders. (d), 827.
Leete, E. Elected Hon. Treasurer. 1086.
Lefroy, H. P. T. Developments in direction-finding apparatus. (d), 1072.
Leggett, B. Premium awarded to. 795.
Leigh, F. A. Cortez, and Say, M. G. Progress in electric traction. (p), 167.
Lejeune, S. M. Students' Premium awarded to. 942.
Library, Council's report on. 757.
——, donors to. 1231.
——, Lending, catalogue, new edition of. 412.
——, Reference, accessions to. 85.
——, Reference, closing of. 941.
Lieb, J. W. Obituary notice. 1535.
Lighting. (*Also see* Illumination *and* Lamp.)
——, electric, for automobiles, progress in. S. P. Smith, (p), 159.
——, electric, progress in. C. G. M. New, (p), 148.
—— fixtures and modern lighting, meeting of Design and Industries Association to discuss. 1530.
—— systems, design of. H. R. S. McWhirter, (p), 1017.
Lightning surges, measurement of. S. W. Melsom, A. N. Arman and W. Bibby, (p), 1482.
—— surges on transmission lines. H. Norinder, (p), 525.
Lines, overhead. (*See* Overhead.)
Linstow, F. N. Heating of buildings by thermal storage. (d), 686.
Lipman, C. L. Instrument transformers. (d), 723.
Load levellers. J. W. Beauchamp, (p), 154.
Local Centres. (*See* Centres.)
—— Hon. Secretary for Italy, L. Emanueli appointed. 314, 756.
Locomotives, electric. (*Also see* Traction, Electric.)
——, electric, progress in. F. A. C. Leigh and M. G. Say, (p), 167.
Logan, E. A. Plant of Imperial Chemical Industries at Billingham. (d), 1284.
Long, T. A. Loading of transformers on thermal basis. (p), 1516.
Longbottom, Sir Benjamin. Obituary notice. 1535.
Longman, R. M.
  Alternating-current potentiometers. (d), 362.
  Jet-wave rectifier. (d), 977.
  Plant of Imperial Chemical Industries at Billingham. (d), 1283.
Lorraine steelworks, electric plant of. L. A. E. Sékutowicz and A. Evain, (p), 413; (d), 428.
Losses, power, in unarmoured single-conductor cables, discussion on. 408.
——, power, of 3-phase overhead lines. P. D. Morgan and S. Whitehead, (p), 367; (d), 778.
——, sheath, in single-conductor cables, discussion on. 409.
Lowey, S. Heating of buildings by thermal storage. (d), 694.
Lucas, H. J.
  Piezo-electric crystal as frequency standard. (p), 855; (d), 871.
  Valve-maintained quartz oscillator. (d), 870.
Lunn, A. L.
  Low-temperature carbonization of fuel. (d), 853.
  Voltage control of large alternators. (d), 789.
Lunnon, F. C. Naval wireless telegraph communications. (d), 260.

M.

McEwen, S. Low-temperature carbonization of fuel. (p), 205; (d), 232, 647.
Macfarlane, J. E. Measurement of noise of machinery. (d), 780.

Mathias, F. V. L. Construction of the "grid" system. (D), 310.
Maxwell, presentation of oil painting of. 199, 753.
Mayo, C. G. Metering arrangements for the "grid." (D), 1505.
Mayo, C. G., and Wellings, J. G. Instrument transformers. (P), 704; (D), 730.
Mayston, W. H. Obituary notice. 1536.
Measurement, high-frequency resistance. W. Jackson, (P), 296.
Measurement, hysteresis, on straight bars and strips. C. E. Webb and L. H. Ford, (P), 1018.
——, need of. B. A. Robinson, (P), 41.
—— of high voltages. R. Davis, G. W. Bowdler and W. G. Standring, (P), 1222.
—— of noise of machinery. B. A. G. Churcher and A. J. King, (P), 97; (D), 125, 780.
——, power-factor, at high voltages. E. H. Rayner, W. G. Standring, R. Davis and G. W. Bowdler, (P), 1132; (D), 1142.
——, precise a.c., accessory apparatus for. R. S. J. Spilsbury and A. H. M. Arnold, (P), 889; (D), 906.
Measuring apparatus, value of. E. W. Marchant, (p), 55.
Medal, Faraday. (*See* Faraday Medal.)
——, Kelvin. (*See* Kelvin Medal.)
Meeting, Annual General, 1930, proceedings of. 1528.
——, joint, of Institution and Local Centres by land lines and loud-speakers. 81, 753.
——, Summer, 1929, Council's report on. 754.
——, Summer, 1930, announcement of. 201.
Meetings, discussions at. 83, 1530.
—— held, list of. 753, 760.
——, Informal, Council's report on. 754.
——, Informal, proceedings of. 412, 1087.
——, Institution, proceedings of. 81, 198, 412, 794, 1231, 1527.
——, Meter and Instrument Section, proceedings of. 202, 942, 1232.
——, Wireless Section, proceedings of. 202, 521, 1368.
Mellonie, S. R. Instrument transformers. (D), 730.
Melsom, S. W., Arman, A. N., and Bibby, W.
  Premium awarded to. 795.
  Surge investigations on transmission lines. (P), 1476; (D), 1495.
Member, Honorary, Sir Richard Glazebrook elected. 314, 752, 1231.
Members, deceased, list of. 752.
——, deceased, obituary notices of. 1531.
——, honours conferred on. 752.
——, new list of. 1368.
—— overseas, activities of, Council's report on. 756.
——, retired, subscriptions of. 314, 757.
Membership of Institution. 751, 760; F. W. Purse, (d), 1528.
Merz, C. H. Plant of Imperial Chemical Industries at Billingham. (D), 1276.
Metals, electric conduction in. D. Owen, (p), 136.
——, electron theory of, recent advances in. R. H. Fowler, (P), 1469.
Meter and Instrument Section, Address of E. W. Hill as chairman of. 24.
—— and Instrument Section, Council's report on. 753.
—— and Instrument Section Premiums, award of. 941.
—— and Instrument Section, proceedings of. 202, 942, 1232.
Metering arrangements for "grid" transmission system. C. W. Marshall, (P), 1497; (D), 1503.
Meters and electricity supply tariffs. J. W. Beauchamp, (p), 154.
——, electricity. E. W. Hill, (P), 24.
——, electricity, bearings of, discussion on. 1519.
——, induction watt-hour, frequency variations in. A. E. Moore and W. T. Slater, (P), 1023; (D), 1033, 1523.
——, testing of. C. V. Drysdale, (p), 352.
Meyers, A. L. A.C. tests on high-speed telegraph cables. (D), 1084.
Mica, variation in thermal resistivity of. (p), 1341.
Microphones, absolute calibration of. B. A. G. Churcher and A. J. King, (p), 107.

Measurements on long telephone lines. A. Rosen, (P), 499.
Pressures on diaphragm of condenser transmitter. W. West, (P), 441.
Science and telegraphy and telephony. E. W. Marchant, (p), 52.
Temperature-rise curves of transformers. T. A. Long, (p), 1516.
—— determination of electrical machines from short heating tests. E. Hughes, (P), 932.
—— of electrical machines, measurement of. E. Hughes, (p), 912.
Testing bent permanent magnets. C. E. Webb and L. H. Ford, (P), 773.
—— by a.c. potentiometer. C. V. Drysdale, (p), 350.
—— instrument transformers, null method of. G. F. Shotter, (P), 873; (D), 906.
—— of current transformers. W. E. Bruges, (P), 305.
——, precision, of current transformers. A. H. M. Arnold, (P), 898; (D), 906.
Tests, a.c., on high-speed telegraph cables. E. W. Smith, (P), 447; (D), 1084.
——, heating, on electrical machines. E. Hughes, (P), 912.
——, short heating, temperature-rise from. E. Hughes, (P), 932.
—— on high-power switchgear. L. C. Grant, (p), 1089.
—— on thermal resistivity of solid dielectrics. (p), 1314.
Thermal resistivity of solid dielectrics (E.R.A. Report). (P), 1313.
—— storage, electric heating by. S. E. Monkhouse and L. C. Grant, (P), 657; (D), 676, 1078.
Thermionic valve. (*See* Wireless.)
Thermo-electric effects, theory of. R. H. Fowler, (p), 1472.
Thomas, H. A. Measuring performance of radio receivers. (P), 475; (D), 493.
Thompson (Silvanus) Premium awarded to E. H. Rayner, W. G. Standring, R. Davis and G. W. Bowdler. 941.
Thompson, W. G. Students' Premium awarded to. 941.
Thornton, W. M.
Breaking performance of high-power switchgear. (D), 1121.
Jet-wave rectifier. (D), 971.
Thorrowgood Scholarship awarded to J. F. H. Tyler. 1530.
Topley, H. Voltage control of large alternators. (D), 789.
Towers, H. C. Railway electrical signalling apparatus. (P), 1507.
Towers for 3-phase overhead transmission lines. P. D. Morgan and S. Whitehead, (p), 370.
Track circuits, notes on. H. C. Towers, (p), 1507.
Traction, Electric.
Diesel engine applied to railway traction, discussion on. 504.
Interference between traction and communication circuits (E.R.A. Report). (p), 597.
Progress in electric traction. F. A. C. Leigh and M. G. Say, (P), 167.
Railway electrical signalling apparatus. H. C. Towers, (P), 1507.
—— traction, jet-wave rectifier for. J. Hartmann, (d), 985.
Tramways, electric, progress in. F. A. C. Leigh and M. G. Say, (p), 169.
Transfers. 86, 198, 315, 524, 656, 800, 943, 1088.
Transformers, current, precision testing of. A. H. M. Arnold, (P), 898; (D), 906.

Transformers, current, testing of. W. E. BRUGES, (P), 305.
—— for Serra hydro-electric development. R. W. H. COUZENS, (p), 1295.
——, high-ratio current. R. S. J. SPILSBURY and A. H. M. ARNOLD, (p), 894.
——, high-voltage, measurement of voltage ratio and phase angle of. G. YOGANANDAM, (P), 192.
——, instrument. J. G. WELLINGS and C. G. MAYO, (P), 704; (D), 719.
——, instrument, null method of testing. G. F. SHOTTER, (P), 873; (D), 906.
——, loading of, on thermal basis. T. A. LONG, (P), 1516.
——, phase-shifting, theory of. C. V. DRYSDALE, (p), 358.
——, progress in. A. R. EVEREST, (p), 142.
——, testing of, by a.c. potentiometer. C. V. DRYSDALE, (p), 354.
Transmission, power. (*See* Overhead lines *and also* POWER SUPPLY.)
Transmitters, condenser, pressures on diaphragm of. W. WEST, (P), 441.
——, telegraph, developments in. H. H. HARRISON, (p), 1400.
——, wireless. (*See* WIRELESS.)
TRENCHAM, H.
  Breaking performance of high-power switchgear. (D), 1114.
  Instrument transformers. (D), 724.
TRICKETT, D. A. Measurement of noise of machinery. (D), 784.
Trolley omnibuses, progress in. F. A. C. LEIGH and M. G. SAY, (p), 169.
Turbines, steam, *versus* gas engines. L. A. E. SÉKUTOWICZ and A. EVAIN, (p), 426; I. S. MACKENZIE, (d), 428.
Turbo-alternator plant of Imperial Chemical Industries at Billingham. H. A. HUMPHREY, D. M. BUIST and J. W. BANSALL, (p), 1257.
Turbo-electric drive for ships. A. R. EVEREST, (p), 145.
TURNER. H. C. Instrument transformers. (D), 726.
TURNER, L. B. Naval wireless telegraph communications. (D), 260.
TURNER, P. K.
  Broadcasting transmitting station for dual programmes. (D), 1171.
  Measuring performance of radio receivers. (D), 490.
TURNEY, T. H.
  Construction of the " grid " system. (D), 311.
  Developments in machine systems. (D), 1464.
TYLER, J. F. H. Thorrowgood Scholarship awarded to. 1530.

U.

Unit, telephone transmission. Sir THOMAS PURVES, (p), 9.

V.

Valve, wireless. (*See* WIRELESS.)
Vehicles, internal-combustion electric, progress in. F. A. C. LEIGH and M. G. SAY, (p), 167.
——, motor, electrical equipment of, progress in. S. P. SMITH, (P), 156.
VIGOUREUX, J. E. P.
  Duddell Premium awarded to. 795.
  Piezo-electric crystal as frequency standard. (D), 870.
  Valve-maintained quartz oscillator. (P), 265; (D), 872.
Voltage, distribution, Council's statement on standardization of. 516, 757.
—— dividers, electrostatic. S. W. MELSOM, A. N. ARMAN and W. BIBBY, (p), 1479.
—— drop of brush contacts. H. G. TAYLOR, (p), 1358.
——, high, a.c. generation at, discussion on. 410.
Voltage, high, measurement of. R. DAVIS, G. W. BOWDLER and W. G. STANDRING, (P), 1222.
——, high, power-factor measurements at. E. H. RAYNER, W. G. STANDRING, R. DAVIS and G. W. BOWDLER, (P), 1132; (D), 1142.
——, surge, on transmission lines. S. W. MELSOM, A. N, ARMAN and W. BIBBY, (P), 1476; (D), 1486.
Voltmeter, thermionic, developments of. E. B. MOULLIN, (P), 1039.

W.

WAINWRIGHT, H. A. David Hughes Scholarship awarded to. 1530.
WALKER, H. W. Address as chairman of Sheffield Sub-Centre. 73.
WALKER, V. Pulverized fuel in power stations. (D), 510.
War Thanksgiving Research Fund grants:—
  1929. J. A. CLEGG. 83, 755.
  1929. A. F. WILKINS. 83, 755.
  1930. F. J. CLARK. 1530.
  1930. (Miss) W. HACKETT. 1530.
WARD, R. G. Jet-wave rectifier. (D), 977.
WARREN, A. G. Measuring performance of radio receivers. (D), 491.
WARREN, T. R. Plant of Imperial Chemical Industries at Billingham. (D), 1277, 1283.
WARRINGTON-MORRIS, A. D.
  Developments in direction-finding apparatus. (D), 1072.
  Piezo-electric crystal as frequency standard. (D), 867.
Water heating, electric, progress in. C. G. M. NEW, (P), 150.
—— heating, electrode method of. S. E. MONKHOUSE and L. C. GRANT, (p), 658.
—— penetration in lead-sheathed power cables. E. A. BEAVIS, (P), 434; (D), 1082.
—— power. (*See* Hydro-electric.)
WATLINGTON, V. Elected Member of Council. 1086.
WATSON, J. F. Power-factor measurements at high voltages. (D), 1146.
WEBB, C. E., and FORD, L. H.
  Hysteresis measurements on straight bars and strips. (P), 1018.
  Testing bent permanent magnets. (P), 773.
WEBB, J. K. Power-factor measurements at high voltages. (D), 1146.
WEDMORE, E. B.
  Breaking performance of high-power switchgear. (D), 1111.
  Surge investigations on transmission lines. (D), 1486.
WEDMORE, E. B., MORGAN, P. D., and WHITEHEAD, S.
  Study of 3-phase system of unarmoured single-conductor cables. (D), 408.
WEEKS, E. G., and SMYTHE, E. H.
  Low-temperature carbonization of fuel. (P), 219; (D), 233, 235, 648, 854.
  Premium awarded to. 795.
WELBOURN, B. Construction of the " grid " system. (D), 308.
WELLINGS, J. G., and MAYO, C. G. Instrument transformers. (P), 704; (D), 730.
WEST, W.
  Measurement of noise of machinery. (D), 129.
  Premium awarded to. 795.
  Pressures on diaphragm of condenser transmitter. (P), 441.
WHEATCROFT, E. L. E. Jet-wave rectifier. (D), 976.
WHITEHEAD, G. E. Breaking performance of high-power switchgear. (D), 1125.
WHITEHEAD, S., and MORGAN, P. D. Impedance, etc., of 3-phase overhead lines. (P), 367; (D), 778.

WHITEHEAD, S., WEDMORE, E. B., and MORGAN, P. D. Study of 3-phase system of unarmoured single-conductor cables. (D), 408.
WHITNEY, W. B. Breaking performance of high-power switchgear. (D), 1115.
WILKINS, A. F. War Thanksgiving Research Fund grant to. 83, 755.
WILKINSON, C. D. Low-temperature carbonization of fuel. (D), 234.
WILKINSON, E.
  Ferranti Scholarship awarded to. 1530.
  Surge investigations on transmission lines. (D), 1494.
WILLIAMS, ALAN. Speaking at Annual General Meeting, 1930. 1529.
WILLIAMS, B.
  Piezo-electric crystal as frequency standard. (D), 869.
  Valve-maintained quartz oscillator. (D), 869.
WILLIAMS, F. H.
  Heating of buildings by thermal storage. (D), 688.
  Measurement of noise of machinery. (D), 782.
WILLIAMS, J. H.
  Speaking at Annual General Meeting, 1930. 1529.
  Vote of thanks to Sir Thomas Purves for inaugural address. 82.
WILLIAMS, R. C. G., and MALLETT, E. Measuring mechanical impedance. (P), 560.
WILLIS, A. M. Measurement of noise of machinery. (D), 781.
WILMOT, R. H. A.C. generation at high voltages. (D), 410.
WILMOTTE, R. M.
  Formulæ for radiation distribution of antennæ. (P), 1174.
  Radiation distribution of antennæ in vertical planes. (P), 1191.
WILSON, J. Diesel engine applied to railway traction. (D), 504.
WILSON, J. W. Developments in machine telegraph systems. (D), 1460.
WILSON, W. Protection of 3-phase lines and feeders. (D), 839.
WINCH, G. T.
  Awarded Page Prize. 1530.
  Direct-reading photo-electric photometer. (P), 533.
WINFIELD, F. C.
  Plant of Imperial Chemical Industries at Billingham. (D), 1280.
  Protection of 3-phase lines and feeders. (D), 840.
  Voltage control of large alternators. (D), 788.
WIRELESS.
  Ammeter for very high frequencies. C. L. FORTESCUE and L. A. MOXON, (P), 556; E. B. MOULLIN, (P), 544; (D), 1173.
  Apparatus development. C. E. KENNEDY-PURVIS, (p), 20.
  Broadcasting transmitting station for dual programmes. P. P. ECKERSLEY and N. ASHBRIDGE, (P), 1149; (D), 1170.
  Design of gramophone pick-up. G. W. SUTTON, (P), 466.
  Developments in direction-finding apparatus. R. H. BARFIELD, (P), 1052; (D), 1069.
  —— of thermionic voltmeter. E. B. MOULLIN, (P), 1039.
  Formulæ for radiation distribution of antennæ. R. M. WILMOTTE, (P), 1174.
  Frequency stabilization of valve oscillators. E. MALLETT, (P), 578.
  High-frequency resistance measurement. W. JACKSON, (P), 296.
  Measurements in Cornwall of signal strength from 5XX. J. H. REYNER, (P), 181.
WIRELESS (*continued*).
  Measuring performance of radio receivers. H. A. THOMAS, (P), 475; (D), 490.
  Naval wireless-telegraph communications. G. SHEARING and J. W. S. DORLING, (P), 237; (D), 259.
  Oscillator, valve-maintained quartz. J. E. P. VIGOUREUX, (P), 265; (D), 867.
  Piezo-electric crystal as frequency standard. H. J. LUCAS, (P), 855; (D), 867.
  Progress in wireless communication. C. E. KENNEDY-PURVIS, (P), 16.
  Quartz-crystal controlled transmitter. G. SHEARING and J. W. S. DORLING, (p), 249.
  Radiation distribution of antennæ in vertical planes. R. M. WILMOTTE, (P), 1191.
  —— curve of loud-speaker. B. A. G. CHURCHER and A. J. KING, (p), 122.
  —— curves of electrical circuits. C. L. FORTESCUE and F. RALPH, (P), 583.
  Science and wireless telegraphy. E. W. MARCHANT, (p), 53.
  Thermionic valve potentiometer. W. S. STUART, (P), 769.
  Transatlantic radio telephony. Sir THOMAS PURVES, (p), 13.
  Wireless Section, Address of C. E. KENNEDY-PURVIS as chairman of. 16.
  —— Section Committee, 1929–30, constitution of. 84.
  —— Section Committee, nominations for election to. 1368.
  —— Section, Council's report on. 753.
  —— Section Premiums, award of, for 1929–30. 795.
  —— Section, proceedings of. 202, 521, 1368.
  —— telegraphy in Merchant Marine. C. E. KENNEDY-PURVIS, (p), 22.
Wiring diagram of São Caetano station. R. W. H. COUZENS, (p), 1299.
—— diagrams for railway signalling apparatus. H. C. TOWERS, (p), 1507.
——, electric, of automobiles, progress in. S. P. SMITH, (p), 157.
—— schemes, assisted, progress in. C. G. M. NEW, (p), 150.
—— Regulations, Council's report on. 758.
—— Regulations, revised Supplement to 9th Edition. 795.
WOOD, K. L. Developments in machine telegraph systems. (D), 1456.
WOODHOUSE, W. B. Vote of thanks to Col. Edgcumbe for services as President. 81.
WOODLAND, R. Page Prize awarded to. 83.
WOODS, R. C. Low-temperature carbonization of fuel. (D), 235.
WRIGHT, JOHNSTONE, and MARSHALL, C. W. Construction of the "grid" system. (D), 311.
WYNESS, W. Low-temperature carbonization of fuel. (D), 234.

X.

X-ray progress. D. OWEN, (p), 135.

Y.

YOGANANDAM, G. Measurement of voltage ratio and phase angle of transformers. (P), 192.

Z.

ZAK, F. J., and EDGERTON, H. E. Pulling into step of synchronous motor. (P), 1205.
